HYSTERICAL SYMPTOMS:

MODES OF INDUCTION IN WAR AND PEACE; SUGGESTION IN NORMALS, IN CONFUSED, AND IN MYTHOMANIACAL SIMULATORS.

BY TOM A. WILLIAMS, M.B., C.M.,

WASHINGTON, D. C.

LATE ADVISER IN NEUROLOGY, AMERICAN RED CROSS IN FRANCE; CORRESPONDING MEMBER, SOCIÉTÉ DE NEUROLOGIE DE PARIS, OF THE ACADEMY OF MEDICINE OF RIO DE JANEIRO, ETC.

THERE are three important types of pithiatism, which it is advantageous to differentiate and keep in mind in dealing with individual cases, for although the mechanism is fundamentally one of suggestion in each case, yet the management must differ in accordance with the contingent conditions. These three types are: (1) produced by suggestion; (2) post-confusional autosuggestion; (3) suggestion in mythomaniacs.

I. *Produced by suggestion,* direct or indirect. In practice these need not be distinguished, the direct being the exception.

Spoken.—In times of epidemic disease, if the symptoms become known, they are experienced by many persons who are not suffering from the disease. This illustrates the spoken suggestion.

By Imitation.—The effects of suggestion by imitation are seen in the comparatively common instances of a paralysis acquired by some one in sound health through association with a paralytic.

Starting at a noise has been the basis of many a phobia of "shell-shock." This applies particularly to men who have not suffered from the effects of severe explosions. It cannot be too widely known that to start at a loud noise is an exceedingly common and natural reaction and has no especial significance whatever. All of us start at noises when our nerves are on edge. Some people habitually do so. It is very wrong to permit soldiers to believe that there is any special significance, that they in particular start at noises and that such a practice is the least indication of pathological instability.

CASE I.—*Phobia of Wild Animals with Impulsions to Flight.*—A boy eight years old had developed hallucinations, which occurred only when he was alone, and whenever he was alone. The hallucinations were accompanied by a loud cry and a twisting backwards of the neck and contortion of the body, so that a distinguished professor regarded him as epileptic. His father and maternal uncle are declared to have had similar attacks in childhood. The mother was overanxious about the boy and hysterical and uneasy when he was out of her sight, and it was this anxiety on the part of the mother of which the boy was well aware, that brought about this unhappy condition in the little fellow. Examination showed no physical signs of disease of the nervous or any other system. In an amnesis, I found him to be a very sensible little boy. My questioning soon showed that the hallucinations were not true ones and that the little fellow never actually saw, felt, nor heard what he feared.

Treatment.—Since he clearly recognized that he had actually never seen anything to be afraid of, it was a simple task to convince him that the wild animals he feared were only imagined, that, in fact, there was nothing to fear and that he was quite safe even when alone. It was impressed upon him that he must learn to be a manly boy and to depend upon himself. To learn not to be so timid, firstly he was told to go out alone every day. First, half a block, then a whole block and finally around the corner, all the time remembering the need of manly behavior; secondly, that he must go to sleep alone so as not to be such a trouble to his parents; thirdly, he was shown exercises to suppress the wriggling tendencies of his body.

Having convinced the child of the unreasonableness of his fears, the parents, especially the mother, were dealt with rationally. It was explained to them that his trouble was phobia against fear—an affective state induced by the idea that something dreadful might happen to a little boy unprotected by grownups—an idea induced by the foolish anxiety of his mother. His morbid reaction had become a habit, which with practice in self-reliance as outlined could be overcome. As a result no further attacks have occurred for 8 years.

Management.—The management of the symptoms which have occurred as a result of mediate or immediate suggestion in patients who have not been confused and are not of mythomaniac constitution is, as a rule, very simple. The chief measures, according to the cause, are:

1. Direct suggestion by means of the spoken word with strong affirmation.

2. Direct suggestion combined with persuasive explanation of the condition, according to the patient's means of understanding.

3. Indirect suggestion by (a) In the case of locomotor difficulty, causing the patient to be trotted round the room by relays of assistants until he becomes so fatigued that he automatically falls into normal progression. (b) Medical measures, such as electricity. (c) Imitation, such as by the watching of the improvement of other patients under treatment. (d) The indirect suggestion of the milieu and discipline to which the patient is subjected in the special surroundings of the neurological center. (e) Deprivation of pleasures or privileges, such as liberty, food, etc. (f) Isolation. (g) The discomforts to which the patient finds himself subjected under a special regime of severe discipline, or painful treatment.

4. Rational persuasion with or without suggestion in the more intelligent patients. In some cases combined with or followed by

5. Special re-educative measures designed to overcome vicious attitudes or defective movements.

II. *Post-confusional autosuggestion.* — With re-

gard to this second type, post-confusional autosuggestion, the following points are of importance. When the first obnubilation begins to cease and while inertia still reigns, there is marked suggestibility due to a lack of synthesis of impressions of the new with the old. This over-suggestibility varies from time to time in accordance with the metabolic condition of the organism. Any toxic cause may aggravate it, as may any further traumatism. But it is also aggravated by the repercussion of a strong impression, such as may be produced by bad news or fear, which prevents attention to other matters and thereby impedes synthesis. This is a phenomenon which occurs not only in the confused but in the normal individual. Familiar examples are examination fright, social embarrassment, dominance by prestige or impressive surroundings. In addition to the psychological trend induced by the powerful stimulus demanding attention, there are to be considered modifications of the reactions of the vegetative nervous system, which modify the cenesthesis and thereby still further deviate attention.

Case II.—*Psychoneurosis after illness; writer's palsy of tremulous type.* A naval paymaster after undergoing an operation for appendicitis returned to work before having fully recovered his strength. An uncontrollable trembling of the hand ensued making the signing of checks, which was part of his duty, almost impossible.

Examination one month later showed that in drawing or lettering there was scarcely a tremor, that the trouble was confined entirely to writing. This disability to sign his name was traced to the fact that the bank had refused one of his checks on account of his tremulous signature, this having been signed when still in his weakened condition after the operation. Thereafter, thanks to his overconsciousness, every signature was made under great apprehension. Here it was not the work itself which was the cause of psychosis, but the patient's attitude toward it, derived from his mental habitus, this being environmental from instances of his youth.

Treatment.—The role of mental prepossession in inhibiting the due coordination of muscular movements was explained to him, and illustrated by means of the strokes in lawn tennis, more especially that known as the drive. It was shown that fear of making an improper stroke is very likely to lead to lack of freedom and cramping the muscles, which are the very positions to be avoided. Still greater anxiety will create an uncertain, wobbling stroke, the incoordination of which is comparable to his writing.

A further illustration was used, that of Jastrow's investigation showing that the relative efficiency of two sets of employees using an enumerating machine in 1900 was in inverse proportion to the stress laid upon its complicatedness in the instructions received by them. Those who received no special training rapidly surpassed in amount of work those who were too conscientiously trained.

The relation of these facts to the episode of the refused check was discussed with him at length. When he had clearly realized the psychological mechanism of his condition, he was directed to entirely cease writing with purpose, and to begin exercises by making free-arm movements with chalk on a black-board, paying no attention to the forms he drew, but concentrating himself upon the attainment of freedom in action. At the end of a month's practice after only one interview he had almost entirely recovered. Two years later the trouble had not returned.

When to Avoid Psychotherapy.—Hypersuggestibility during toxic obnubilation should never be dealt with psychotherapeutically. Such efforts only do harm by making a demand upon the patient of which he is incapable. They will give him only confused, disorderly, and necessarily harmful impressions, which may perpetuate in his imagination the disquietudes he feels, and the vaguely uncomfortable ideas about the strange condition in which he feels himself. Such patients should be let alone to the utmost as regards any attempt at re-education, and psychotherapy should be confined to the simplest of assurances and more especially to those conveyed by gesture and manner; for it should be remembered that these means of communication are more fundamental and easy of apprehension than is the more highly elaborated artifice of the spoken word. It must also be remembered that a considerable number of people, just as do children and the lower animals, gain most of their important impressions, especially about the character and intentions of other people, from the gesture and manner of these people rather than from their words, and this is especially the case where the degree of education has not been very high.

Hence, extreme solicitude before such patients is most harmful, in that it is very likely to give rise in their minds to the notion that they are very sick indeed, a notion which produces depressing emotions which will still further interfere with good metabolism. Whereas an affectation of indifference before the patient will tend to make him think that the doctor would surely pay him more attention if he were really as sick as he feels. Hence, though uncomfortable, he will be contented in feeling that if his case demands so little attention it must be one which will soon recover. The spirit of hope thus engendered will go far to help him both to enjoy his food to digest it well, besides accelerating the metabolism by favorably affecting the vegetative nervous system.

The mechanism differs in *psychic shock*, which does not produce actual but only seeming inertia, by deviation of energy from the mental synthesis needed for the situation to be adapted toward the preoccupying thought to which mental energy may be given. The extreme of this is seen in paranoia, where it has led to almost complete absorption, without, however, necessarily any morbid suggestibility; but this is because the delusions have become adapted to, indeed *are* the life, and do not give constant emotion, and the patient is, when excited, hardly distractable at all.[2]

In post-confusional inertia, however, there is no mono-ideaism in the usual sense. The patient simply has not the psychic activity needed for synthesis—association is only rudimentary and so he cannot call upon resistances and criticisms. Hence, he is usually dominated by a single impression and becomes thus a fertile field for suggestion, either from without or from the rudimentary mental life within which usually assumes the character of what is known as onirism, namely, the dream-life. The patient wears the aspect of being in a trance, and his thoughts flow with the apparent incoherence

and confusion of a dream, which usually assumes the character of his profession or other main life interest.

This state is most commonly caused by cerebral intoxication, as is well known, more especially in that of febrile disease. But it is capable of being caused by trauma, and is typical of the condition known as cerebral commotion. See description in forthcoming book, also *Bost. Med. Jour.* (to appear)

The repercussion upon the organism of a powerful emotion, too, my cause a shock so severe as to make the patient incapable of complicated association, besides diverting his attention, whereby mental synthesis is greatly impaired, and suggestibility becomes exalted. Such emotion as sudden bad news, a sudden fright, or a long-continued strain as before an important ordeal, the emotion produced by social embarrassment, the dominance by impressive surroundings, the prestige of the person with whom one is dealing, are all factors which diminish synthetic capability, and add to suggestibility by creating a temporary confusion.[3]

III. *The Mythomaniac.* — The characteristics of this condition are: (1) Extreme susceptibility to immediate surroundings. (2) Lack of continuity of purpose. (3) The incapacity for accurate statement to the degree of pathological lying. (4) Often an exuberance of fancy and inventiveness. (5) A lack of stability or character, showing itself by erratic behavior. (6) Often immorality, especially as regards honesty and fidelity.

These characteristics date from early childhood. They are rooted in the character of the individual, and hence are not amenable to the kind of psychotherapy available in the army. They would necessitate a remaking of the character, a long and difficult process, requiring very special means and measures which are really available only under the best conditions. Even were every resource at our command, we could not be sure of success at a period of life when the character is generally definitely crystallized. Such patients while under care may seem to progress satisfactorily, but when they are again among the difficult problems of daily living, unprotected by relatives or friends, they quickly succumb to the evil influences which they are certain to encounter.

In the induction of the mythomanic syndrome, the common motive in civil life is vanity. In war there is often substituted the more fundamental motive of self-preservation. The desire for a "Blighty one" becomes very strong in certain temperaments. It is only the difficulty of doing so severely enough and in a likely way, in conjunction with the fear of being found out, which prevents men of this kind from mutilating themselves to escape danger.

The degree to which such motives can lead, even in peace, is familiar to medico-legal experts. A striking example is one related by Dupré, wherein a man caused himself to be laparotomized three times for a supposed tuberculous peritonitis which he simulated by means of abdominal tympanization, pains, digestive troubles, etc. The general opinion what that he was an hysteric. Dupré, however, studied him carefully, and many times caught him in intentional lying, and not only caused him to simulate at will the classic forms of hysteria, such as complete hemianesthesia, until an unexpected prick administered under the bedclothes revealed the fraud, but atypic and contradictory syndromes which he organized according to the traps which were set for him, for the pleasure of the deceit and to render himself interesting in the eyes of those around him. The patient was an accomplished mythomaniac, and can be quoted as a good example of simulation pushed for the love of it to the extent of repeated laparotomy.

Now, this man derived a certain esthetic pleasure from his conduct. It would not be too much to call it artistic. He was truly a mythomaniac of action.

Even, however, where no pleasure is received

Photograph of a soldier who has several convulsive attacks a day, during which he bites himself at the places on the arm. The marks on the legs and forehead he declares are made by knocking himself against surrounding objects. Notice the symmetrical distribution of the injuries. The patient has no stigmata of epilepsy. He is perfectly lucid. There is no irascibility, no dullness. After the attacks there is no somnolence and there is never involuntary micturition or biting of the tongue, and the attacks never occur during the night. The patient is a mythomanic, pseudo-epileptic.

from mythomaniac acts, a patient's desire to escape from danger or punishment may provide a motive strong enough to preponderate against the most cruel moral suffering, as in the soldier who simulated deaf-mutism for seven months, and who was so terrified that he would lose his voice that he would go into a dark passage in the evening in order to murmur words to himself, and who related after he had confessed, how intensely he had suffered (Sicard).

It is safe to say that, if an individual of this type has not been kept straight by the discipline and *esprit de corps* of army life, any time and skill spent upon his treatment will be at the ex-

pense of other patients to whom it might be more usefully dedicated.

Hence, the best military disposition of such cases is discharge from the service. Unless, indeed, it is considered wise to utilize their labor as auxiliaries in a corps under special discipline.

In the milder cases, however, where adaptation before the breakdown was not impossible, it is worth while for the psychiatrist to add his understanding and weight to the more impersonal and casual influence of troop morale. If re-education of attitude makes progress the man may become fit to be a soldier again.

It is from patients of these tendencies that malingerers and simulators arise. In many persons, good upbringing has dwarfed the antisocial inclinations of indifference to truth, and slovenliness toward obligation; the fear of consequences has restrained erratic ways; and the need to earn a living has given a certain appearance of stability which breaks down when without proper surveillance. Such individuals find too often the chance for the reassertion of these antisocial tendencies. The wise army doctor is on his guard against them.

Mythomania. — Mythomania, according to E. Dupré's definition, is the pathological tendency, more or less conscious or voluntary, toward falsehood and fabulation—that is, the power of creating imaginary stories. It differs from the ordinary untruth and from simulation. The states due to mythomania are more or less intimately related to hysteria, but must not be confused with it, still less with dementia.

Generally speaking, mythomania results from the lack of control which in normal individuals is constituted by intellectual criticism, moral sense, and voluntary inhibition.

It is generally associated with other psychic defects, such as vanity, malignancy, perversity actuated by vicious appetites and instincts.

Normal Mythomania in Childhood. — Wonder, fear, lack of experience, and a superabundance of creative spirit give to the ordinary child something of the mythical power which, of old, belonged to primitive men. Mythomania of the most spontaneous kind seems to be normal in childhood and corresponds to the period when the equilibrium of the faculties has not yet been reached.

In normal individuals this mythical tendency is conquered at the age of puberty. When it survives in the grown-up individual it may be considered as a pathological defect.

Experimental psychology has established as a fact that accuracy of testimony is quite exceptional in childhood. Veracity is difficult to attain and the causes are exaggeration resulting from the imperfect justness of precepts or from the activity of the creative imagination, and in many cases suggestion by others.

Sometimes children are impelled to lie by occasional causes, such as fear of blame or childish boastfulness. This last motive is sometimes the first step to simulation and fabulation. For intance, a boy of eight beat and bruised himself to make believe a struggle with thieves in which he would have been the hero. Another boy gives false news to get consideration and to have the pride of seeming better informed than any of his comrades.

Negation of the truth when produced spontaneously by some exterior motive leads frequently, by a process of autosuggestion, to a false affirmation, generally independent from the primitive factor of denying the truth.

Simulation is rare with the ordinary child; it is generally ephemeral and connected with another form of deceit.

Fabulation, which is the power of inventing romanesque situations and adventures and of dramatizing the child's own life, is the highest form of the mythical activity of his mind. Many instances occur of very young children relating with the utmost accuracy of details some facts that they could not possibly have witnessed.

Pathological Mythomania. — There is nothing pathological at all in such working of the undeveloped mind. Pathology appears when the excess of duration and intensity gives an abnormal character to these mythical manifestations. It is a sign of degeneracy and is generally associated with other symptoms of psychical disequilibrium.

In children, several classes of facts may be considered:

The first class derives from a kind of morbid vanity and is the exaggeration of the above-mentioned tendency toward becoming a hero. This inspires migrations, flights to the neighboring wood or to the seaports. It takes also the more dangerous form of autoaccusation of imaginary crimes.

The second class is malignant and is actuated by the destructive instinct, suggesting calumny, heteroaccusation, or more complex tales accompanied with simulation.

The young monsters supply deficiency of their minds and their debility by the qualities of the animal mentality, cunning, slyness, ferocity. They invent tales of martyrdom suffered by them, accuse their own parents with a great luxury of details, and seem to enjoy the sanguinary or salacious quality of the stories. They are happy to occupy public opinion and to accomplish mischief. False martyr children, little accusators, are recruited among them.

In some cases the only motive is so childish, and there is such a disproportion between the aim and the effort displayed that it reveals more weakness of mind than real moral perversity.

The best instance of that is a case quoted by Motet, of a little girl who started the most monstrous denunciation against an innocent man. When cross-examined by the judge and asked about her motive for such denunciation, she answered candidly that she wanted to sit in the beautiful armchairs which had been described to her by a young comrade.

Very frequent are false tales of rape.

Perverse mythomania is even more important in adults.

An important feature of these cases is the part played by suggestion, either parental or from strangers. Many morbid tales are directly inspired in children by the indiscreet and probing questioning of their parents—when they come back late from school, for instance. A very curious case showing the importance of suggestion in constructive imaginary power is related by Bourdin. A little abandoned girl of five was adopted by Mr. and

Mrs. X—— and admitted to live in the intimacy of the family. One day they read the paper aloud, and commented in her presence upon a most scandalous trial, supposing the child incapable of following their conversation. A few days later Mrs. X—— caught the child performing obscenities to her doll. In answer to her anxious questions, she said she was doing what had been done to herself and immediately built up a tale accusing her foster-brother, father, and grandfather. The medical examination proved the emptiness of the child's declarations, who finally confessed having been prompted to imitate "the ladies quoted in the newspaper."

Another instance is of a boy of nine who accused himself and other persons of having participated in erotic orgies. Finally, after the medical examination which proved his sexual inability and the falseness of his evidence, he confessed that nothing of the sort had ever taken place and that only obscene questions had pushed him to invent all these details.

This process of fabulation by suggestion may be attributed, first, to the extreme suggestibility of the child, stimulated by vanity or fear; secondly, according to the remark of Vibert, to sloth of his will, which dictates the easiest answers by yes or no; and, lastly, to the unconsciousness of the serious consequences of his accusations. The passive attitude of the child can bring him to a testimony entirely void of reality. There is commonly a mixture of inventive activity and passive suggestion of original creation and borrowing from the persons around.

The conclusion is that error more frequently than truth is found in the mouths of children.

Mythomania in the Adult.—The mythomanical syndrome, by its etiology and morbid associations, is the same in the child and in the adult, but it acquires a greater importance in the latter from the higher intellectual development of the subject and from the more complex social relations and interests. This tendency, as we have said before, is a survival of the childish mood. It is more frequent in youth, and the majority of cases are in young women or girls.

The same varieties of manifestations that have been analyzed in the case of children can be distinguished: Alteration of the truth, falsehood, simulation, fabulation. Simulation becomes a preponderant element.

Alteration of the truth is manifested not only by the lack of veracity in narratives, but also by variations and contradictions in successive accounts of the same facts. They are generally involuntary, unconscious and spontaneous. If discussed, they show in their author a partial amnesia of what he had said before and the lack of accuracy of perception and of criticism. In many cases, however, the fidelity of the first narrative is quite remarkable and convincing to jurists not aware of this quality.

Experiments made by L. W. Stern on subjects from 18 to 24 show that 11 per cent. of sworn testimony is false, and that correctness of remembrance is exceptional. These experiments throw a light on the embryonic form of mythomania.

More differentiated is the habitual tendency to falsehood, the motives of which are boastful impulses, malignant wishes, or different kinds of perverse desires.

Simulation of disease is an autonomous morbid process frequently associated with mental alienation or crime. It is also one of the favorite means used by the mythomaniac to strengthen the likelihood of his stories.

It may be considered as an "active fabulation" and betrays in simulators an extraordinary ability made of the aptitude to imitate, united to presence of mind, tenacity, and a voluntary domination of the organic plasticity.

The highest degree, the most differentiated form of mythomania, is fantastic fabulation, and its psychological and medico-legal interest is much greater in adults than in children.

This tendency arises from vanity, malignity, and perversity. Instances may be classified under these three headings:

Mythomania from Vanity.—A morbid appetite of vain story produces in the weakminded boaster real paroxysms of lying. The most frequent form is fantastical boasting or bragging, of which literary types have been given in "Tartarin de Tarascon," by Daudet, and "Le Menteur," by Corneille.

They are true virtuosi of falsehood, often without admixture of malignity in their motives.

Another variety of the same type, much more interesting from a medico-legal point of view, is criminal autoaccusation. The authors are either debilitated subjects of very poor originality, finding inspiration in the newspapers, or more intelligent people building up very complicated stories. The motives are the same as in the case of mere boasters; they want to attract the attention of people in order to arouse indignation or pity. Sometimes a grain of malice, of a puerile rather than a dangerous character, enters into their pleasure. They enjoy the fact that they are able to deceive dtoctors, judges, and public opinion. Many examples may be given.

Motet quotes the instances of a youth who pretended to be the murderer of his sister. According to his story, he had caused asphyxia by introducing carbon dioxide into her room through a rubber pipe adapted to an apparatus constructed by himself. He certainly prided himself on this complicated and quasiscientific scheme, the absurdity of which was a proof the debility of his mind. After being sent back a first time to his family, he accused himself a second time; but when he saw that no credit was given to his romance and that he had been kept in jail for five days, he confessed that he had committed no crime and that his sister had died of illness.

Dupré observed a young man of 24 who confessed to being the murderer of a man who had been found cut to pieces at Ménilmontant. His parents declared that he was a liar, a braggart, always planning absurd and impossible things.

Arundel quotes the case of a young girl who cut herself above the left breast, and tried to persuade people that she had been assaulted in a train. The result of the inquest was negative, and it was discovered that the knife used by the imaginary murder had been bought by the victim herself a month before.

This kind of mythomania compels some subjects

to automutilations and sometimes to simulation of illness.

In the same category may be placed simulations of criminal attempts made without malicious intention.

In one case, Baroness de X. simulated a swoon and to persuade her husband that masked men had come during the evening, threatened her and robbed her of 2,000 francs. The facts seemed highly improbable, and after a few days she avowed that there had been no criminal attempt and that she could not give any reasons why she had simulated aggression and burglary. It is interesting to remark that a few days before the newspapers had published details about a burglary committed by masked men in Belgium and that suggestion had probably inspired the drama imagined by Baroness de X.

Dupré relates the cases of a maid found by her mistress gagged and bleeding in a disordered apartment, and of a man who complained of having been run over by a cart and hurt seriously enough to necessitate laparotomy. No motive could be found for their accusations. In both cases inquiry showed hysterical stigmata, and it was found that two years previously the maid had already stimulated death in the presence of her lover and that the man had already pretended having been the victim of a railway accident in which he had suffered serious internal injuries.

These observations show a curious mixture of complicated fabulation with simulation of the setting of the drama. They show also that in such patients, submission to surgical operations may be included in their plan of deceit.

Malignant Mythomania.—This form is in many ways similar to the previous one, but a malicious intention is mixed with the other motives. Destructive instinct at all degrees manifests itself in the choice of means and in the choice of victims. It had been observed to be more frequent in woman. The instances range from mere hoaxing to the most dangerous forms of slanderous accusations.

Anonymous letters are often the tool used by these mystificators or accusers and this choice proves better than anything that vanity is overreached by maliciousness. They are often accompanied by simulation.

Dally quotes the case of a young girl who simulated death during three days and enjoyed thoroughly the efforts, threatening, and prayers of the people surrounding her. He relates in the same study the simulation of a blepharospasm by a young woman, who was believed to be affected by convulsive hysteria. This patient, who after a complete recovery has become a very intelligent woman and an excellent mother, confessed to her doctor her simulation, which, according to her, was an irresistible impulse.

Many persons taken for hysterial subjects are simply conscious and malicious organizers of spiritism or other manifestations of pseudo-occultism.

From these cases we pass to calumnious hetero-accusation. Numerous cases exist which implicate the innocent in crime. The motives are sometimes hatred, jealousy, revenge. But there is always a great disproportion between the intial motive and the maneuvers directed against the victim.

P. Garnier published a case of this variety of hetero-accusation with second offense. A weak-minded girl of 19, an hysteric, accused three persons of having drowned a man. She brought about a condemnation, which happily was revised in the court of appeals. Sometime after, she accused her own father of the same crime. The drama ended by an attack of convulsive hysteria.

In such a case suggestion counts for nothing and the foremost elements have a propensity to falsehood a morbid desire of injuring others, added to a violent and actual rancour.

The most curious variety of malicious fabulation in adults is genital hetero-accusation directed against innocent people. The informer accuses of rape, violence, mutilations, dramatic adultery, sometimes even a pregnancy and criminal abortion. All the classical characteristics of the so-said hysterical accusation are united: apparent lucidity and sincerity of the informer, plentifulness of details, mysteriousness of the drama.

Very often there is a double hero and the informer is also his self-accuser, hysterical people going so far as to immolate themselves for the sake of falsehood.

Examples abound in medicolegal literature of these criminal romances invented by mythomaniacs and generally imputed by hysteria because their authors have hysterical stigmata or accidents.

A classical instance is found in the indictment of Lieutenant de la Boncière in 1835. He was accused of rape by Mlle. de Morel, condemned to ten years of close confinement and was not rehabilitated until 1840.

A more recent one reproduces the same facts. A country girl of 22, an hysteric, was found one morning in her bed half fainting with a bloody cut across the neck, her feet and neck bound with a string. She related a scene of rape and accused of the deed a young man of the same village who had aroused her rancour by disdaining her. Later on she was brought by Garnier to confess her deceit, but she remained indifferent to the enormity of the lie she had told.

The choice of crime is almost always rape, although sometimes murder or robbery appears with a direct accusation.

Perverse Mythomania.—Perverse mythomania is actuated by vicious motives, most frequently cupidity or lust. It is generally the most complex of all the forms.

Cupidity is a very strong stimulus. Famous swindlers, stock-jobbers, discounters of future heirlooms or fortunes, are very often mythomaniacs of great spread. They cram their stories with figures and contrive to make them appear real. Such were the famous Therèse Humbert case in France, and the Chadwick case in America. All nations can present such adventurers, and Delbrück thought that such a type of pathological falsehood was important enough to be characterized by a special name, fantastical pseudologia.

The most interesting side of these inventions is the success they find with uncritical people, the security of the liar, the sincerity of the look, the strength of his own conviction impress people so much that he raises proselytes. These proselytes, in their turn, suggest the faith and confidence he was

clever enough to give and react upon himself. It is a curious instance of mutual suggestion and collective psychopathy, as seen in many pseudoreligious sects even in our own day.

The several forms of perverse mythomania create such types as polygamous husbands, who succeed in marrying different persons in different places, and professional seducers who make their way by feigned chivalrous manners.

Relations between Hysteria and Mythomania.— Both are constituted by simulation, either provoked or spontaneous, of a fact nonexistent in itself.

It is perhaps illegitimate to group under the same name facts as dissimilar as convulsive attacks, narrowing of the field of vision, hemianesthesia, and the tendency to falsehood. The disassociation of the hysterical block seems necessary.

There are, however, common characteristics of hysterical facts and mythopathic facts. Both are constituted by the stimulation, either provoked or spontaneous, of a fact nonexistent in itself. In the hysteric the simulated fact belongs in most cases to the pathological order, and objectives itself with a synergical participation of mind and body, under the form of a neuropathical syndrome.

In the mythomane, the simulated fact is of a more general sociological character. It is completed with the help of language, with a collaboration of other organic activities, and becomes a more or less complicated story.

Accordingly, the differentiation would be that in the case of hysteria, the facts are unconscious and involuntary and in the case of simulation they are conscious and partly voluntary. But in both cases, autosuggestion exists and whether its processus be active or passive, in both cases the clinical result is the same.

There is no accurate means of measuring or appreciating the intention or consciousness. In the majority of cases, the problem remains insoluble. Neurological clinics, as well as medicolegal and penitentiary records abound with these hybrid classifications. Hence the need of a separate category, mythomania, with the definition: "A constitutional tendency to falsehood, *more or less conscious and voluntary.*"

Some conditions, physiological or pathological, create a temporary state of mental disequilibrium presenting some similarity with the mythomathiac syndrome; oniric trancelike states, postoniric fixed ideas, and that form of senile dementia called by Wernicke presbyophrenia. Some intoxications, especially chronic morphinism, predispose also to falsehood and fabulation.

These different states are interesting to compare with mythomania proper, tothrow a light upon the pathogenic conditions of the most voluntary and conscious forms of fantastical fabulation. But the frontiers of conscious fraud are difficult to trace, they depend upon the cleverness of the mythomane and the want of criticism on the part of the observer.

Medicolegal Conclusions. — Such a study is important not only from the psychological point of view, but still more for the practical and social interests it offers to the medical jurist.

The testimony of a child ought always to be considered as suspect. There always ought to be a critical research of the part played by suggestion. The duty of the medical jurist is to enlighten magistrates as to this lack of reliability of children's testimony.

The medical study of adult mythomanes is also important in the light of justice. A number of the above-stated cases brought about the indictment of an innocent person, a legal inquest, and sometimes a condemnation. Slanderous auto and hetero-accusations ought to be detected. Magistrates, when in the presence of some well-known forms of accusation, emanating from certain types of persons, ought to have a suspicion of the danger and ask for the intervention of the medical expert. His study of the case is a valuable, and sometimes an indispensable means of information, and in many cases it is sufficient to give the medicolegal clue to a problem, apart from the legal inquiry.

In such cases there is more truth in pathological explanations than in the judicial interpretations of lawyers. The time has already come when modern psychiatry is substituting in the mind of the law its scientific conclusions for the superannuated principles of the old philosophy.

THE VALUE OF LABORATORY EXAMINATIONS IN DIAGNOSIS AND PROGNOSIS IN OTO-LARYNGOLOGY.*

By SEYMOUR OPPENHEIMER, M.D., F.A.C.S.,

NEW YORK.

ASSOCIATE OTOLOGIST, MT. SINAI HOSPITAL; CONSULTING OTOLOGIST AT WILLARD PARKER HOSPITAL; CONSULTING OTOLOGIST AT GOUVERNEUR HOSPITAL

AND

HENRY JAMES SPENCER, M.D.,

NEW YORK.

DIRECTOR OF THE LABORATORY FOR CLINICAL RESEARCH.

The vital importance of the relationship existing between the laboratory technician and the oto-laryngologist is too well known to need emphasis or substantiation. This relationship well maintained means reliable, logical, scientific practice.

That the results of the laboratory may be trustworthy, it is necessary for the technician, in all but the simplest measures, to have had considerable careful training and a clear knowledge of the import of the examination made. This is becoming increasingly evident. It is no longer true that all men graduated since the colleges entered laboratory courses in the curriculum may become qualified laboratorians. There are those naturally fitted for this work as for any other human occupation.

The laboratory examination as an aid in oto-laryngology is given much less attention than it deserves. The practitioner must be sufficiently

*Presented at the Otological Section of the New York Academy of Medicine, November 14, 1919.

conversant with the methods used to evaluate properly the technician's report, for in the end the successful man is the one who balances the pathological return with the clinical findings and in the light of experience accepts or ignores it.

In the work of our office the laboratory has been a very great ally. We shall give the principal types of examinations made and discuss them in the light of our own experience.

Urine.—The urine examination is now considered almost necessarily a routine procedure. We are concerned here with albuminuria, glycosuria, acetonuria, and the microscopic presence of erythrocytes, pus cells and casts.

It is important that the examination be routine and frequently repeated in some conditions, notably following tonsillitis, and especially in its mild forms. Loeb has clearly pointed out this relationship. He was able to rule out scarlatina and diphtheria in four of the cases he presented; in fact it is interesting to note that in the latter condition the nephritis arises concurrently with the acute disease while it tends to follow the tonsillitis in the cases cited. In his papers he reviewed the findings of several workers and showed that the relationship has been recognized for some time. He referred to the work of Leyden in 1881, who drew attention to that form of so-called acute spontaneous nephritis following exposure to cold and wet, characterized by a slight fever, hematuria, and albuminuria, in which cases he was able to secure a history of tonsillitis very frequently, and he thought it the most important antecedent condition. Morse considered tonsillitis a dangerous disease and advised routine heart and urine examinations following it. Loeb found that the urine changes come on insidiously with very mild albuminuria, with only a few erythrocytes microscopically and with no symptoms except lassitude. The nephritic changes seem to follow mild as readily as severe tonsillitis. Many of the nephritis cases run a mild course to death and a third class have repeated acute exacerbations. One observer reported as high as 75 per cent. of his cases of tonsillitis followed by albuminuria.

The temperature changes which occur in accessory sinus infections can frequently be traced to the pyelitis which is set up as a metastatic process. This is true, too, of suppurative otitic disease. It has not been an infrequent experience to observe small children with an acute otitis, with a high temperature, when the question has arisen as to the necessity of a mastoid operation, in which a careful urinary examination has disclosed a pyelitis as the causative factor and not a mastoid complication. Let us emphasize that you insist upon a quantitative statement of the formed elements without which you cannot form a correct estimate of conditions.

The presence of glucose is important. Prognosis is markedly affected by it. Treatment is made much clearer. If the sugar content of the blood can be lowered, suppurative processes are relatively easily handled. Ordinarily, but not constantly, the rendering of the urine sugar-free is a good index. Occasionally the percentile sugar content of the blood may remain high, although no sugar appears in the urine. This rarely occurs in diabetes and it is here that the condition is most important, rendering infection of the wounds much more likely than in the healthy person, probably on account of two factors: the altered metabolism of the body renders the tissues less resistant to bacterial invasion and the presence of the added glucose in the serous fluids of the body makes them even better culture media despite the bactericidal substances present. In major operative procedures which are not of an urgent nature such as a mastoid of not a very acute type, laboratory control of the results of dieting and medication of the patient to determine the most advisable moment to undertake operation can be readily carried out and renders the prognosis of the case much better.

Acetonuria is of variable import. Whether an associated diabetes exists should be carefully determined. It may follow anesthesia. Its importance lies in the fact that it may indicate an acidosis so grave that it accounts for symptoms or contraindicates operative interference for the time. The determination of the carbon dioxide capacity of the blood plasma measures for us the gravity of an existing acidosis.

Blood.—The importance of determining the coagulation and bleeding time has been pointed out in a previous paper. It concerns those cases where there is any suspicion of the existence of hemophilia or purpura. Unless predetermined, an unwarranted risk is assumed. The methods in use, while open to some theoretical objections, are serviceable and give the information wanted. Each method has its own average time which should be known and which may vary considerably from other methods. Practically all of them are simple and rapidly carried out.

In the observation of some 500 patients, it was observed that the coagulation time might be prolonged and the bleeding time normal or vice versa; in fact, the authors were much impressed by the frequency of protracted bleeding time in individuals who showed a normal coagulation time. This brings up a most important point in connection with an operative procedure to be undertaken.

The chemical blood examinations are coming into greater and greater prominence. They will be treated later in this paper.

The value of the blood count is well proven. Both the total and differential estimates of the white blood cells are valuable and always will be so despite the frequent publication of cases where no help was derived. A further aid is secured by reducing the differential estimates to whole numbers rather than percentages or by applying one of the diagrammatic methods advocated by Gibson and Sondern. From time to time, the erythrocyte count and the hemoglobin estimation will prove of value.

In obscure suppurative conditions, as, for example, in a mastoid under suspicion, a progressive polynuclear count may prove to be the determining factor in advising operation. The leucocyte count forms a good index as to the resistance of the individual.

Sputum.—A sputum examination should mean a great deal more than it usually does and should be performed much oftener. Well does one of us remember facing a patient who had a mass on one vocal cord, who had been examined by four laryn-

gologists of repute, as well as a widely known surgeon, who could not agree in the absence of definite physical signs as to whether the diagnosis was syphilis, carcinoma, or tuberculosis. In five minutes a sputum examination settled the matter beyond doubt.

An examination should always give a good idea of the predominating organism or organisms as determined by smears; should include the gross characteristics, such as color, odor, sedimentation, elastic tissue, Curschmann's spirals and the microscopic presence of blood, cosinophiles, and so forth, and very frequently should employ cultures to check up the results of the smears. Such an examination would be a real aid in determining pneumococcus types, in fixing asthmatic cases as bronchial in type, and in differentiating bronchial and pulmonary conditions.

Spinal Fluid.—The findings secured by lumbar puncture are of great help bacteriologically following otitic disease. The cytological examination should never be omitted, as it alone may determine a concurrent condition of importance. The test for reducing-substances is of some aid in indicating whether an inflammatory process exists. The globulin tests, of which Noguchi's is the more sensitive, give some information.

Oppenheimer has pointed out the important aid to diagnosis secured by lumbar puncture. While recognizing the dangers of the procedure he demonstrates its value in cases where doubt exists as to the process taking place. With a positive fluid the intracranial and intraspinal condition can be quickly determined and the prognosis possibly favorably changed by timely action. Changes discovered early make successful operation much more possible.

Only localized meningitis or abscess will give a negative fluid. In the face of negative findings, depending upon clinical conditions, one may wait and repeat the puncture later. High pressure of the fluid is very important. Normal or low pressures may mean nothing. The finding of organisms, especially the tubercle bacillus, is conclusive evidence. Normally six to eight cells per cubic millimeter are found and are almost all of the mononuclear type. Suppurative conditions yield a polynucleosis. Increased lymphocytes suggest tuberculosis, poliomyelitis, or lues. Brain tumors and brain abscesses frequently cause only an increase of the pressure.

Serological Tests.—Serological examinations of the blood, spinal fluid and the serous effusions are now so widely used and so numerous that their value needs no emphasis.

Despite the fact that the Wassermann test for syphilis has been severely attacked for the thirteen years of its life, it has steadily held and gained a following. Theoretically we know its weakness. Practically, above all opposition, it has proven of value. A great danger, however, lies in the unquestioned acceptance of its results. Conscientious serologists are urging a standardization of technique, rather than a development of modifications of the original technique. The method is not foolproof yet, and incompetent technicians are giving cause for much of the distrust of the test and should not be tolerated. Many of them seem to have no conception of exactness of working. In our work the test has undoubtedly proven a great aid in determining what certain obscure conditions may be due to.

In reviewing our case histories, having performed the Wassermann reaction as a general routine over the past two years, we find a series of thirteen patients whose blood sera gave a very strongly positive reaction, who showed no signs which would be suggestive of syphilitic lesions in the nose, throat, or ear. Another group of twenty-one cases was found whose complement fixation reaction was very strongly positive and who were suffering with the following conditions: One case of a tumor of the auditory canal, two cases of perforation of the nasal septum, four cases of suppurative ethmoiditis, two cases of leucoplakia, two cases of sound perceptive deafness, one case of ulceration of the mucocutaneous juncture of the nose, one case of optic neuritis, three cases of marked hemicrania, supposedly referable to the nose; one case of chronic suppuration of the maxillary sinus, and one case of fissure of the lip. One does not presume too much in making the statement that the great majority of these patients would not have had a proper diagnosis made if it were not for the fact that Wassermann tests were made as a routine measure.

The more recently developed serological tests for pertussis and tuberculosis are theoretically sound. As yet the latter can be considered only an aid because the reaction may be given by an arrested case. The result must be checked carefully by clinical observation and in doubt should not be accepted without reservation. The pertussis test gives results early enough in the disease in a fairly large percentage of cases to make it well worth applying.

Complement fixation tests are now being used for determining the specific proteins that asthmatics and hay-fever patients are anaphylactic to. The tests are performed with specific antigens prepared from the animal, vegetable, and bacterial substances which may play a part in a given case. Their value has not yet been established.

Almost all of these tests are open to the objection that they are not localizing in their results and therefore may not indicate what a particular focal process is due to.

Bacteriological Examinations.— Two principal types of study are applied here, the first by smears and the second by cultures.

Smears demand more care and attention than they are ordinarily given. They are in competent hands of the greatest aid and the oto-laryngologist who fails to make several on each case so that appropriate stains may be applied, fails to use a valuable method. The Gram stain, too often improperly applied, gives an abundance of information. Bennett points out its value as 'showing the type of predominating organism, where in culture the organism might be swamped by faster growing varieties; 'showing phagocytosis of a given organism, thus indicating the one for which a vaccine should be prepared; 'to indicate the effect of a vaccine in use. He found that the organisms could often be classed with accuracy by smear, all of his work being checked up by careful cultures. The

fusiform organism of Vincent's angina can only be secured by smear, as it does not grow on any known medium. He found the smear of value in prognosis also because of the ability to differentiate simple, easily yielding conditions as those due to *M. catarrhalis*, from more stubborn ones, as those due to the streptococci. The fusiform organism always meant necrosis.

The bacterial flora varies greatly with the part studied, its state, and the methods employed in studying it. Thus the nasal cavity of the normal healthy person contains very few organisms and those often in pure culture, seldom more than three kinds. Logan Turner has pointed this out and states that these are usually not virulent. The healthy accessory sinuses are most frequently found sterile. In catarrhal conditions the staphylococci, streptococci, pneumococcus, *Micrococcus catarrhalis*, *B. influenzæ*, meningococcus, Klebs-Loeffler bacillus, and tubercle bacillus are important invaders.

In the mouth a much greater variety is of course found upon the mucous surface, but when the tonsils are enucleated and the organisms of the depths of the crypts studied relatively few species are found and these in pure culture or small mixed groupings. Thus Maclay found that staphylococci, streptococci, and pneumococci occurred in a pure culture in that order of frequency in 87 out of 268 cultures. Negative smears meant nothing, as growths were commonly secured despite them. Moreover, the smear might show a certain organism predominating, while in culture another would promptly overgrow it. Tubercle bacilli were found by smear only once, and never by culture, for Guinea pig inoculation was not attempted. We know how often this last method has proven valuable in work of numerous investigators. Hemolytic streptococci were determined seventeen times, but the viridans only once, which Maclay thinks was an error which would be corrected by using proper blood plates.

Cultures.—Cultures are of great value when positive. When negative it is perhaps best to disregard them in most cases. At times they are of great help, for example, in tuberculosis, erysipelas, and acute rheumatic fever, in ruling out possibilities. These statements do not hold, however, in the case of blood cultures. Here, a positive or negative culture is always significant, as we have pointed out in a previous paper.

Lake distinguishes between a bacteriema, where living organisms are practically continuously in the blood stream, and a pyemia, in which their presence is casual. The clinical picture is usually clearly different. The prognosis depends largely on the basic condition. Bacteriema which is rare in other bone diseases is not so with mastoid conditions, but in our experience has not been seen unless a complicating sinus thrombosis existed.

Oppenheimer, after stating the necessity of early operation in lateral sinus thrombosis, points out the characteristic phlebitic symptoms associated with mastoid disease and advises operation in the presence of a positive blood culture, especially if of the streptococcus group.

In another paper, Oppenheimer has pointed out the value of blood cultures in metastatic complications of suppurative otitis media, especially in conditions due to streptococcus simulating acute rheumatic fever. In five cases, in which the otitic condition had been somewhat lost sight of in the presence of an acute polyarthritis, blood cultures were positive and a sinus thrombosis was found. In one of the cases later blood cultures were positive despite the fact that the jugular ligation and exsection had been performed. At autopsy vegetations yielding the same streptococcus recovered from the ear and sinus were found upon the heart valves. In this case streptococci were recovered by aspiration from the knee joint. The routine employment of blood cultures in many acute febrile conditions would undoubtedly clear up many an obscure, unsatisfactory diagnosis and probably would render the prognosis also more obvious in many of them.

The information which is derived from the laboratory in the taking of blood cultures in a case of otitic disease cannot be overestimated. The negative findings, as well as positive ones, offer much guidance to the clinician.

The detection of a bacteriemia should be possible in every case of sinus thrombosis at some time during the course of the disease, although it is possible that as the result of various causes such as a sterile thrombosis situated below the infected clot, for a time at least, might prevent a bacteriemia from becoming evident; or the culture may be taken before the bacteria are thrown off into the circulation; in the latter instance, if the culture were taken a few hours later, the organisms would be found. It is also possible that the powers of hemic resistance are greatly increased, and all of the circulating bacteria might be caused to disappear within a comparatively short time by a highly developed bactericidal power of the circulating fluid or it is possible that there may be such a small number of organisms in the blood that in the minute quantity examined, they may not be found.

Following a mastoid operation where a sinus thrombosis is suspected, but where symptoms are not sufficiently definite to warrant opening the sinus, and a blood culture has given negative results, it is most essential that subsequent cultures be taken. This method will be found of great value in clearing up an obscure case that might not be relieved by operation until a much later period. The rule can be laid down that in the presence of streptococci in the blood stream there is a septic focus and that further operative measures are necessary.

In the case where the sigmoid sinus has been attacked but the jugular vein has not been ligated, the persistence of a possible blood culture is an imperative indication for the ligation of the jugular vein. Should positive cultures remain after the jugular ligation, it would be suggestive of a bacterial infection of the endocardium or a metastatic process in the lung.

In our experience, dealing with approximately 150 cases of sinus thrombosis we have never observed an infection due to any organism other than the *Streptococcus mucosus*. This point has proven of very great value in forming an opinion in many instances, and shows the importance of making a

culture from the pus contained in the mastoid process at the time of the operation. For example, we have seen a number of cases where the infection in the mastoid was of the pneumococcus type and where, after the mastoid operation, symptoms presented themselves which were suggestive of a complicating sinus thrombosis. The blood cultures were negative.

In counseling against operation upon the sinus in these cases, our patience was rewarded by seeing subsequently developed pneumonia, erysipelas, or some other complicating condition which explained the symptomatology so much akin to that found in sinus thrombosis. One can see, therefore, the significance of the negative blood culture in conjunction with a nonstreptococcic type of infection.

In conclusion, we may say that cultures from nasal or tonsillar secretion or otitic pus, blood, spinal fluid, and the like, give a great deal of valuable information which, carefully studied, makes the prognosis clearer, and in addition may form the starting point for the preparation of autogenous vaccines which, properly prepared and administered, provide us with one of our best methods for combating infection.

Tissue Examinations.—Joseph Beck of Chicago has repeatedly emphasized the value of the examination of material from mastoid operations. He is able to distinguish two types of acute mastoid involvement which he classified as (*a*) the cell route type, which bleeds freely on operating, is soft, has most of the septa destroyed, the bone appearing as chips in the swollen mucous membrane, and heals rapidly; and (*b*) the vascular type, which bleeds little, is firmer, but otherwise appears the same in the gross, the bone undergoing slow necrosis because of a minute thrombosis in which healing is much delayed by the necessity for the necrosed parts to separate. The streptococcus and *Micrococcus catarrhalis* are the commoner organisms in the latter type, as against the staphylococcus, pneumococcus, and *Bacillus influenzæ* in the first. Here then the etiology is of great importance. The laboratory aids in diagnosis and prognosis.

In chronic conditions the examination is equally important in distinguishing fibrous from cholesteatomatous, tuberculous, neoplastic, and other conditions, while serological tests clear up the cause for the sluggish healing of the luetic cases.

Likewise many workers have found examination of the lymphoid tissue of the nasopharyngeal and faucial regions of great help in diagnosing tuberculous conditions.

Cutaneous Tests.—Certain cutaneous tests have now been developed which play an important part at times. The von Pirquet is the oldest of the group. In children it is undoubtedly of value whether negative or positive; in adults it is so seldom negative that one is tempted to ignore it completely. It is so simple and so quickly done that in appropriate puzzling cases it should be applied with due allowance for its limitations. The less sensitive tuberculin tests, such as the Moro test, may prove more valuable in adults in the long run.

The luetin test is rarely used because of the cost and the readily available Wassermann test.

The Schick test is of the greatest value in prognosis. Care must be exercised in applying the test. The diphtheria toxin is readily secured and with care will keep for about six months. When diluted it should not be kept over twenty-four hours.

The specific proteins have recently come into use for diagnosing the particular causative agent acting in a case of pollen disease or bronchial asthma. Packets may be secured which contains extracts in powdered form of the specific proteins of many substances, both animal and vegetable. These are put in solution and applied to scratches on the skin where reactions to one or more of them may occur indicating some or all of the proteins which affect the patient. This gives opportunity for greater exactness in diagnosis and if desensitization can be carried out, prognosis is improved.

Renal Functional Tests.—The renal functional tests are the outcome of the work of a group of clinicians and physiological chemists, which tests have reached a stage of perfection which warrants their very wide application. *This statement especially applies to all who carry out surgical procedures under general anesthesia.* J. B. Deaver very recently presented some of his figures secured since using two of the tests—blood urea and phenolsulphonephthalein. Of 420 cases (tested) operated upon, 403 were considered suitable and only one died of uremia; 17 were reported unsuitable, and of these, operated upon only as a last resort, 7 died of uremia. The same general results have been secured elsewhere.

The tests referred to are the estimation of the uric acid, urea nitrogen, creatinine, and sometimes sugar, of the blood and the red or phenolsulphonephthalein test. Their use is indicated whereve the urine examination or history presents any suspicion of nephritis or diabetes. The blood chemical tests indicate the grade of kidney injury or the working capacity of the kidney, while the phenolsulphonephthalein test gives only the function of the moment. The blood chemical group is the more important, but the phenolsulphonephthalein test should not be neglected. When kidneys are injured, the uric acid content of the blood arises first and as the injury becomes more grave, the urea nitrogen and then the creatinine are found increased. A rise of the last is of great portent. These tests can now be carried out complete on 10 c.c. of oxalated blood by a very recent method devised by Folin and Wu. The tests should be done by only a well trained chemist, and then they are exact and relatively simple.

Whenever a major surgical operation is being considered and its need is not too urgent, a urine examination showing albumin, casts, pus, blood, or a specific gravity so altered as to arouse suspicion of the functional capacity of the kidneys, should lead one to have the blood examined chemically. If the uric acid or urea is moderately increased no special anxiety need be entertained on this basis, but if the creatinine or sugar or both be raised the prognosis becomes more grave, and especially if the creatinine content rise above 3 mg. per 100 c.c. No person having over 5 mg. has lived many months. These tests can be employed with a resulting much greater sense of security on the part of the surgeon.

We have presented those tests with which we

are most familiar and which have proven useful upon employment in our work. There are undoubtedly others which we have overlooked.

This does not weaken our contention that the practice of medicine, including our specialty, is uncertain enough even with every safeguard thrown about it for us not to ignore these very valuable aids. In the last analysis, as we have pointed out, the clinical picture is equally important, and in case of a conflict between the two, that man who studies and employs both thoughtfully is the one who will best be able to decide which to take as his guide at the critical moment.

COMMENTS ON THE FUNCTION AND CLINICAL USES OF THE PINEAL GLAND.*

By WILLIAM N. BERKELEY, A.B., Ph.B., M.D.,
NEW YORK.
ATTENDING PHYSICIAN AT THE GOOD SAMARITAN DISPENSARY.

THE anatomy of the pineal gland may be found in any of the standard textbooks. An exhaustive treatise on the morphology, evolutionary significance, pathology, and clinical relations of the gland is in course of publication by Tilney and Warren.[1] It is not my purpose to touch on the morphology here except to express the belief (reasons for which will appear below) that the gland, while relatively more active in early life, does not, as supposed by some, atrophy with sexual maturity. It evidently retains through life a fairly definite size, and any function it may possess in infancy is probably not altogether abrogated in adult years.

As a matter of some clinical and diagnostic interest we may note, parenthetically, the observation of Schüller of Vienna[11] that after calcification of the gland has occurred, pineal shadows will appear in profile *x*-ray photos of the skull—about 1 cm. behind and 3.5 cm. above the external auditory meatus.

The view was advanced in the last century that the pineal gland anatomically is only a vestigial remnant of a third eye, occipitally situated, and still to be observed in certain reptiles. Whatever be its evolutionary relations the opinion is constantly gaining ground among clinicians that physiologically it is a true organ of internal secretion. Supporting this conception there are both experimental and clinical data, some of which I shall now proceed in an entirely informal way to set forth.

My interest in the pineal body dates back a number of years, to a time when Dr. C. L. Dana of New York first called my attention to a case of pineal gland tumor reported by Von Hochwart[2] and suggested that some research work on the subject might prove fruitful. Von Hochwart's case was that of a boy of five years, who had projectile vomiting and choked discs—indicative, of course, of cerebral tumor. It was not, however, the presence of a cerebral tumor that was so noteworthy, but that the patient showed a physical and mental precocity far beyond his years. He was as large as a boy of fourteen, had a bass voice, a growth of pubic hair, and concerned himself much with ethical problems and immortality.

Von Hochwart's case has not remained isolated. A succession of tumors of the pineal gland has been subsequently reported in the foreign neurological journals, and by Bell, Warren, Tilney, Dercum, and others in the *Journal of Mental and Nervous Diseases* in this country. The symptomatology of them all has been similar; and nowadays signs of cerebral tumor in the region of the corpora quadrigemina, concurrent with abnormal growth of the body, early appearance of axillary and pubic hair, and remarkable sexual and mental precocity, are grouped definitely as the "pineal syndrome."

To recur, however, to Von Hochwart's case, the autopsy revealed a cellular tumor of the pineal gland. Von Hochwart and his colleagues advanced the view that the pressure of this tumor had inhibited the growth and secretion of the pituitary. But it seemed to Dr. Dana and myself simpler and much more probable that the pineal secretion itself by reason of its increased amount had brought about the extraordinary mental and somatic growth above described.

Working upon this hypothesis for several years, under Dr. Dana's constant and helpful supervision, and with some financial assistance kindly granted us by the Trustees of the Rockefeller Institute, I was able to show that preparations of pineal gland, gotten perfectly fresh from calves and young cattle, accelerated the somatic growth of kittens, rabbits, and guinea pigs to a marked degree, and that a number of backward children, without organic stigmata, to whom the gland was administered for a sufficient period—usually three to six months—

*Revised from an informal address before the Clinical Club, Yonkers, New York.

made an advance in mental age considerably in excess of any previous progress for a like period. The work with the children was conducted not only by Dr. Dana and myself, but by various other observers. Details of the research may be found in the paper finally published by us in the MEDICAL RECORD.[3] This account attracted more than usual attention, if I may judge from the numerous scientific discussions and experiments that have followed. Some (Ruggeri,[9] Biondi[10]) have touched only on the histopathology of the gland, and this will not be discussed here. McCord[4] was able to confirm fully, and to amplify our feeding experiments. Dandy,[5] operating on puppies, from the brains of which by a new surgical method he claimed to have successfully removed the pineal gland, reported that growth proceeded, and sexual maturity appeared as well without the pineal gland as with it. G. Horrax[6], who made extirpation experiments on rats and guinea pigs, claimed that pinealectomy accelerated growth and sexual development in the animals operated on. Fenger[7] extracted pineal glands, and with his extracts was unable to get results of any kind distinguishing his subject animals from the controls.

As regards Fenger's work the chemical details of his extraction processes are not clear enough to admit of a definite opinion being expressed; but it is plainly impossible that the observations of Dandy and Horrax should both be true. I am disposed to think that excision experiments, at all events those of the character so far adopted, involving a profound disturbance of the circulatory and anatomical relations of almost the entire brain, will have to be left out of the story, and that feeding observations and clinical experiences should be given exclusive attention.

Recurring, therefore, to the clinical study of the pineal body, I should like to report summarily that my later work with the gland in backward children in private practice, has continued to be gratifying and satisfactory. The only requirements are that the child should be properly cared for in an educational way, and that the remedy should be continued for a long period—perhaps years instead of months and weeks. There are some fathers and mothers who demand a cure for their abnormal children in a week; for such parents there is nothing ahead but disappointment.

I have brought with me here to-night (there will not be time to read them) notes of six cases of small boys and girls recently in my care who have done very well indeed on pineal gland, their mental progress, in the opinion of their parents, physicians, and teachers having been notably accelerated.

In the care of all such cases one must continually bear in mind that "mental backwardness" in a child is a vague term, covering an infinite multitude of unknown conditions. A careful and minute examination of every feature of each case must be repeatedly made; for outside of the cretins and Mongols, but few generalizations are possible. The prenatal history is often important, and, of course, the character of the labor, and the baby's nutrition and food must be carefully looked into. The child's mental age must be rather accurately determined, and the special senses, the tonsils and adenoids, the teeth (both present condition and stage of eruption), the skin, the blood pressure, the shape of the hands and feet, the quality and distribution of the hair, the relation of the weight and height to the age, are all very important. *X*-ray photos of the skull, showing up the pituitary fossa, and giving possible indications of cysts, neoplasms, or hemorrhages of the brain, are almost indispensable. And, of course, a serological examination of the spinal fluid should be a routine measure, where the parents can be got to consent to it.

When all this work has been carefully done, it will soon become evident to the attentive student—it is no discovery of mine—that glandular deficiencies often do not come singly, and pineal gland must often be tentatively combined with other secretions. Minor grades of hypothyroidism should be specially suspected, and a dry skin, cold extremities, obstinate constipation, excessive mental hebetude, irregular and imperfect eruption of the milk teeth, low blood pressure—one or all of these may be remarkably intractable till thyroid is added to the formula. When the physical as well as mental growth is retarded and there are changes in the size of the sella, or increased carbohydrate tolerance, or great obesity, or a systolic blood pressure below 50 mm., the anterior or the middle part of the pituitary, or both, should be added. When the patient is a boy and has very minute and soft testes (a common occurrence), testis should be given. Sometimes several of these conditions coincide, and a pluriglandular formula of pineal, pituitary, testis (or ovary for girls), and thyroid—all in minute doses—may be tried, often with the most gratifying results.

An important cautionary note should be added as to where such pluriglandular prescriptions—or for that matter prescriptions for any kind of internal secretion—should be procured. One young medical friend telling me recently of his ill success in a certain case said he had sent his patient's mother with the prescription to the nearest pharmacy, directing the pharmacist to "use the very best materials he had." This is something like asking the milkman's advice in making up a formula for a baby with a chronic diarrhea. There are now several New York wholesalers who specialize in internal secretions, and in properly prepared pluriglandular formulas; and if the medical attendant hopes for results in any wise commensurate with his thought and effort in diagnosis he should not be satisfied with any gland preparation unless he is sure it is absolutely fresh and obtained from a well-known and reliable source.

As a means of speeding up the sluggish cerebral chemistry of many backward children, I believe that pineal gland will ultimately become a standard remedy; but the cases must be selected with reasonable care; permanent organic damage to the child's brain is usually an absolute contraindication.

As a corollary to the clinical use of pineal gland in accelerating the chemical movement of the brain in the backward child, it has appeared to me justifiable to try it in premature decay of the mental powers in old people. I have found that while it will not make over hardened arteries or a dilated heart, it will quicken the slowed-down mental processes of old age, improve the memory, and pro-

duce a remarkable cheerfulness and sense of well-being. Some of my elderly patients have taken it for years, and decline to be without it.

In conclusion of this rather disconnected discourse, I must not omit to mention that W. Timme[8] has recently offered some interesting evidence toward proving that progressive muscular dystrophy is an endocrinopathy, and that the pineal gland is the organ at fault in such cases. The paper is too long to be quoted at length, but is worthy of serious consideration. The argument is based partly upon clinical signs, partly upon the appearance of pineal shadows in the *x*-ray photos of the skulls of the patients reported, the said patients being, it is claimed, all too young for calcification to have developed.

HEREDITY AS A FACTOR IN THE ETIOLOGY OF NEOPLASMS.*

By VIRGIL H. MOON, M.Sc., M.D.,

INDIANAPOLIS, IND.

It is not intended in this paper to review the theories concerning the cause of cancer or of new growths in general, nor the various conditions which may act as exciting or contributing causes. We will be concerned only with a presentation and discussion of the evidence which goes to show that hereditary tendency to neoplastic proliferation is an important predisposing cause.

Most of those here present can recall instances in their own experience which illustrate the tendency of tumors to occur more frequently in some families than the average percentage of occurrence per unit of population. I recently performed an autopsy on the body of a man who died of carcinoma of the bladder. His brother, father, grandfather, and one uncle had likewise died of carcinoma. In another instance I was requested by a man to make a post-mortem examination on the body of his brother who had died of pneumonia. His reason for the request was to find if the brother had cancer, as another brother, the father, and one uncle had each died of cancer. The deceased brother had given no evidence of cancer, but autopsy revealed a well developed carcinoma of the stomach. Such a family predisposition to tumors, both benign and malignant, has been noted so frequently that mere coincidence is not a satisfactory explanation of the occurrence.

While such a familial predisposition is recognized by many authorities in pathology and surgery, yet statistical proof is peculiarly difficult for several reasons. In the first place it is practically impossible to trace all the members of a given family through more than two or three generations. To realize this point one has only to try to get from a patient an accurate statement as to just what disease caused the death of each of his parents and grandparents and of the brothers and sisters of those parents and grandparents. Obviously unless all the members of a family can be traced through a number of generations accurate conclusions are not possible. In the second place accurate diagnosis of cancer has been possible during only about one generation. Prior to that time, and even, we regret to admit, at the present time, many cases of carcinoma were diagnosed "stomach trouble," "gallstones," "tuberculosis," "inflammation of the bowels," etc. One has only to make an autopsy examination upon a few hundred cases dying from all causes in a public hospital to realize how frequently the presence of a malignant tumor escapes undetected. For the reasons just stated statistical evidence from death returns and from cancer surveys of a whole community or population is necessarily fragmentary, and while such evidence cannot be regarded as conclusive, yet some very interesting and suggestive features of malignant disease have been shown by statistical study.

A number of investigators have collected figures on this subject, but these must be regarded as representing the minimum rather than the maximum of familial cancer occurrence because of the difficulty of obtaining complete family histories with correct cause of death stated, and because of failure in former years to recognize cancer in every case. In other words it is probable that if the exact truth could be known many more cases have family history of cancer than these figures indicate.

Williams reviewed the histories of 370 female cancer patients and found a family history of cancer in 83, or 22.4 per cent.; 136 cases of mammary cancer had a cancer family history in 24.2 per cent.; 142 cases of uterine cancer had a family history of cancer in 19.7 per cent. Butlin found a family history of cancer in 37 per cent. of his cases, Nunn found such a history in 29.3 per cent., and Lemp in 23 per cent. Warthin, in commenting on these figures, agrees that "In certain families the cancer chances are greatly increased, 15 to 20 times those of individuals of the general population. If the chances of cancer for the individuals of certain families *are* 15 to 20 times greater than for the individuals of the general population, we must concede the existence of a family tendency to cancer, since such high percentages of occurrence in certain family lines cannot be explained on the grounds of environment, infection, or mere coincidence."

It is seen from a chart representing the Mendelian law of heredity that in hybridization of individuals with different hereditary characters a so-

*Read at the twentieth annual session of the Ohio Valley Medical Association at Evansville, Ind., Nov. 11 and 12, 1919.

called recessive character will occur in approximately 25 per cent. of the offspring after the second generation. Levin made a study of the influence of heredity on the occurrence of cancer in a number of cancer families or so-called cancer fraternities. He found that with a cancerous ancestry the percentage of cancerous members corresponds closely with the Mendelian percentage above cited. In eight such families studied the percentage of cancerous members ranged from 10 to 33 per cent., which is a fairly close approximation to the Mendelian ratio of 25 per cent. for a recessive trait in hybridization after the second generation.

I have mentioned the difficulties of securing definite statistical proof of the influence of heredity on cancer occurrence in the human species. Experimental studies on this point are confronted with insurmountable difficulties, because in the human species selective mating is not practicable, and were it possible to control the mating of individuals, the length of time which must elapse before the offspring of even the first generation should arrive at the cancer age would make the problem impossible from the standpoint of experimentation. Fortunately this phase of the problem can be investigated by animal experimentation and if we admit that the same laws of heredity apply to all species the results would seem conclusive. It is found that spontaneous tumors, both benign and malignant, occur in various animals with a fair degree of frequency when the animals are allowed to attain sufficient age. This statement applies to fowls and mammals, both carnivorous and herbivorous. This fact provides a suitable starting point for investigations on the influence which heredity may have on the occurrence of spontaneous tumors in animals.

The most extensive series of observations on this point thus far reported are those of Maud Slye of Chicago, with reference to the occurrence of tumors in mice. A number of reports have been published detailing her observations which are of a most illuminating character. She found that certain strains of mice, kept pure by inbreeding, developed cancer in a high percentage, while other strains, also inbred, never developed tumors of any kind. Her early experiments were concerned with hybridizing or crossing these strains and observing the occurrence of tumors in the offspring. Genealogical records were kept of all the individuals of each strain, and an autopsy was performed on each mouse at death. At the time of her fifth report her experiments had covered a period of more than ten years, and her mouse colonies had a population of more than 12,000 living members. She had performed more than 14,000 autopsies among which occurred more than 2,500 individual primary tumors. Her stock contained three original cancer-bearing families, from which by inbreeding she derived strains which developed cancer in 100 per cent. of all members which lived to cancer age. These cancerous strains and their offspring furnished continuously a supply of from 50 to 100 living cases of cancer. It will be seen from these figures that the quantity of material for observation and experimentation was ample. She had strains of mice which never developed tumors when tested by prolonged inbreeding, and by hybridization with other noncancerous strains. When such nontumorous strains were crossed with cancerous strains she was able to separate from the offspring strains on the one hand which never produced cancer, and on the other hand strains which regularly produced cancer, and which in turn carried cancer occurrence into every strain with which they were crossed. In other words, she was able at will to breed cancer occurrence into a strain of mice which for many generations had been observed to be free from cancer. Also by selective breeding she was able at will to eliminate cancer occurrence from cancer-bearing families whose parentage on one side produced cancer in 100 per cent. of its family members.

She noted that the occurrence of cancer in the offspring of hybridization between cancerous and noncancerous strains paralleled closely the occurrence of a Mendelian recessive trait in similar hybridization. She stated that cancer-bearing mice carry cancer occurrence into strains with which they are hybridized as inevitably as an albino mouse carries albinism into a pigmented strain with which it is hybridized, and with parallel occurrence of the trait in the later generations. So close was this parallelism that she was able to predict with accuracy the percentage of occurrence of cancer in resulting strains from hybridization, and to have the predictions verified as successive members of the strain arrived at cancer age, died, and were examined at autopsy.

Observations on the transmission of cancer from one to another, as by direct contact, were also made but with negative results. Mice of noncancerous parentage, caged with cancerous mice, never developed cancer. The young of noncancerous parentage were allowed to suckle from females with well developed cancer of the mammary glands with uniformly negative results. Noncancerous mice were fed with fresh cancer substance from other mice but without result. Miss Slye concludes as a result of these and other observations that the transmission of cancer has nothing in common with the transmission of infections.

The interpretation which Miss Slye places upon her observations is not that the disease itself is inherited, but that the tendency or potentiality to proliferate in the lawless fashion of neoplasms is transmitted through the germ plasm to the tissues of the offspring. In her hands this has occurred in exact accordance with the laws governing the transmission of any hereditary trait. She believes that the laws of heredity operate with the same inevitability in humans as in mice; that the evidence of its action in humans is obscured by the difficulty of obtaining the facts. In the human species heredity is a highly complex problem because it represents continuous heterogeneous hybridization. Each individual is a heterogeneous complex of hereditary tendencies, both active and latent, which tendencies are transmitted to the offspring in accordance with the same laws which can be demonstrated as operating in other species where experimentation is possible.

It seems probable, in view of the statistical data on the familial occurrence of human neoplasms, and of the experimental data concerning the hereditary occurrence of cancer in animals, that tumor-pro-

ducing potentiality is an hereditary trait. If so, the conditions which are assigned by pathologists as possible causes of cancer probably act merely as exciting or determining factors in individuals who have received a tendency to the neoplastic type of growth as a heritage from their ancestors.

2933 Broadway.

DETERIORATION OF OUR CARDIOVASCULAR STIMULANTS; MEANS OF PRESERVING AND OF INCREASING THEIR THERAPEUTIC EFFICIENCY.*

By ERNEST ZUEBLIN, M.D., F.A.C.P.,

CINCINNATI, OHIO.

ASSOCIATE PROFESSOR OF MEDICINE, UNIVERSITY OF CINCINNATI; RESIDENT MEDICAL DIRECTOR, CINCINNATI TUBERCULOSIS SANITARIUM.

In daily practice we often are disappointed in the extent of our therapeutic results, and whilst such an experience acts as a stimulant to our thoughts to detect the reasons of our failure, we are apt to put the blame on the patient for his or her lack of cooperation or we blame the nature and extent of the pathological changes. Mindful of the strictly observed regulations regarding the preservation, preparation, and dispensing of drugs, as laid down in the recent editions of the pharmacopeia, in only a few instances we are certain that the unsatisfactory therapeutic results can be ascribed to deteriorated drugs or to an improper administration.

Natural science in its further progress has become a vast field of accumulated knowledge, difficult to be grasped and assimilated by the medical man, who, however, would profit by such additional information in many years.

Invited to talk on my own observations as to how to improve our methods of treatment, it gives me great pleasure to bring before the audience a few facts which may prove of value to the medical profession. Bearing in mind the necessity of omiting a number of interesting details and reviewing shortly the principal facts, let us first consider the following questions: (1) the possibility of deterioration of drugs; (2) the tests applied for the detection of such changes apt to interfere with the therapeutic efficiency of pharmaceutical products. (3) the means of prevention of such a loss and deterioration.

1. Do drugs deteriorate? With reference to organic matter we must admit the marked changes which necessarily follow the cessation of life, tending toward disintegration and dissolution. Can we apply this law to the vegetable cells, which, once function has ceased, shrivel up in a process analogous to desiccation? This may be only one interpretation of one phase of a process which reaches beyond our present recognition. Whilst using vegetable drugs, the active principles of which are still inclosed in a bulky substratum, we may be sure that the process of disintegration is not likely to affect the alkaloids proper. Subjecting the vegetable drugs to the different methods of extraction and maceration and digestion we hope to obtain in the solution prepared the active substances in a therapeutically effective form. Practical experience utilized in the pharmacopeia points toward a disintegration, since certain rules are adopted to exclude drugs from therapeutic use after a certain time of storage has elapsed. We see this in dealing with atropine, digitalis principles, and others. Such rules were probably the result of careful observations demonstrating the therapeutic inefficiency of older preparations, as compared to fresh products. Although in the case of organic compounds a change in the physical and chemical properties is not always evident, in inorganic compounds we are well aware of the change in aspect, crystalline or amorphous form, present after the elimination of the water of crystallization. Such changes may be due to dehydrating or oxidizing processes, may be partially due to yet not fully known alteration in the molecular or atomic structure. My former investigation work leads me to the conclusion that inorganic (1, 2, 3, 4) as well as organic matter (4, 5) is subject to constant changes, which to a certain extent may interfere with therapeutic efficiency. Though matter will never perish, it may undergo certain changes which can be demonstrated.

2. Methods of testing for such changes. It is not the purpose to review the tests applied for the detection of changes in the chemical and biological qualities of drugs, but I would like to call your attention to the physical qualities of drugs observed in cardiovascular remedies. Part of my results have already been published, whilst the present facts refer to newer research work of mine.

The apparatus used for the study of the physical properties of drugs was the fontactoscope, used for the purpose of detecting chemical rays, identical or similar to the alpha, beta, and gamma rays produced within and sent forth from the *x*-rays tube or radiating from radioactive substances such as radium, thorium, etc.

The proper reading of the curves to be shown later requires the explanation of a few technical terms as well as a few remarks concerning the technique for a radioscopic test. For comparison the tested substance must always be compared with the radiation present in normal air, which readings are represented by the *normal loss*, charted as a dotted line. We remember that normal air is a mixture of gases—O, N, H, H_2O with the addition of some of the rarer gases such as helium, argon, etc. Physically speaking this mixture of gases consists of ions, positively or negatively charged electrons. They may be free or neutralized or the positive particles united with the negative particles may have become bodies without any electric charge. This process of neutralization becomes more evident in the course of observation. One of the essential parts of the fontactoscope is formed by the electroscope, the leaflets of which may be of gold, silver, or aluminum foil. Suppose we charge the electroscope with positive electricity, the leaflets will fly apart as far as possible, the distance between them being noted down after reading the scale through the eyepiece. The support of the electroscope is in direct connection with the condenser or drum, and consequently carries the same electric charge as the electroscope itself. From the former surface the negatively charged electrons are attracted and with the neutralization of the positive units by the negative units of the air, the electric

*Paper read before the General Practitioners Medical Society, Columbus, Ohio, May 23, 1918.

tension existing between the leaflets of the electroscope is lessened, therefore a fall of the leaflets is noticed. The rapidity of the fall of the leaflets is dependent upon various factors: first, the amount of radioactivity present in the air or substance to

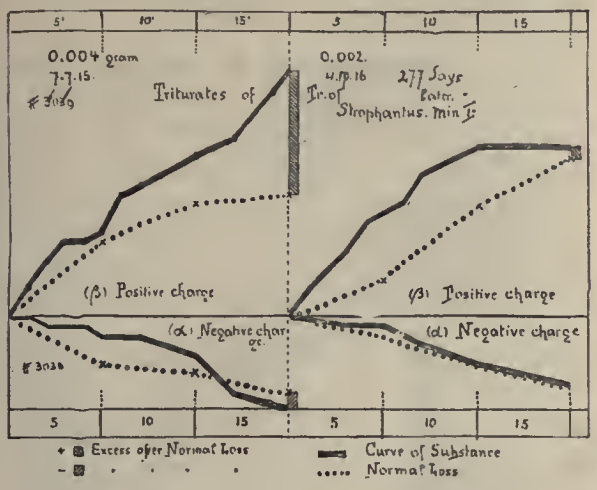

CHART I. CHART II.

be tested, but also dependent upon the size of the condenser drum, expressed by an individual factor determined by the manufacturer of the apparatus. In the air tested we may have a different amount of positive and of negative electrons, one of which being present in excess will necessarily retard the fall of the leaflets; or the case may happen where at first the negative loss is predominating, consequently a different form of the radiation curve is the result. What do we learn from the charts? Starting from the zero point, the readings with a positive charge of the instrument are seen above the zero line. From the study of radioactive bodies we remember that the beta rays carrying a negative charge are neutralized by electropositive electrons, consequently we can speak of the beta line above the zero line, whilst the line below represents the readings with a negative charge of the fontactoscope may serve for the demonstration of alpha rays.

It is not necessary to discuss the methods of separation of these various rays; complete information will be found in the literature.

In former communications I demonstrated the curves of electric discharge observed on samples of various digitalis preparations such as the powdered leaves of digitalis, of triturates of fluid extract of digitalis containing 1 minim of triturates of tincture of digitalis, corresponding to 10 minimis. The result of successive determinations of the same sample of substance made after a lapse of 323 and 459 days in the first instance, after a lapse of 69 to 277 days in the second instance showed that in either instance the positive ionization curve steadily diminished, finally being behind the normal loss. The negative or alpha curve, however, revealed a gradual increase over the normal loss, particularly in the instance of the powdered digitalis leaves. In the same paper I referred to a process which increases the height of the electric discharge curve which tests show the greater ionization in such treated specimens.

In the further pursuance of my experiments I found the following results for strophanthus preparations as illustrated in curves.

Chart I represents in the dotted line the normal loss above the zero line with a positive charge of the fontactoscope. The heavy line represents the curve obtained by the examination of 0.004 gram or 1/15 grain of a crushed tablet triturate of tincture of strophanthus containing 1 minim of the drug. This amount of substance spread in a thin layer and placed within the fontactoscope, then observed for the period of 15 minutes, gave a steep ascending curve, which exceeded considerably the curve of the normal loss. A glance at the alpha curve below the zero line, under a negative charge of the instrument, reveals a normal loss which is less marked. The substance curve at the onset of my observations remains behind the normal loss, but finally exceeds the normal loss. But compared with the positive excess over the normal loss the last observed value stays far behind the first observation.

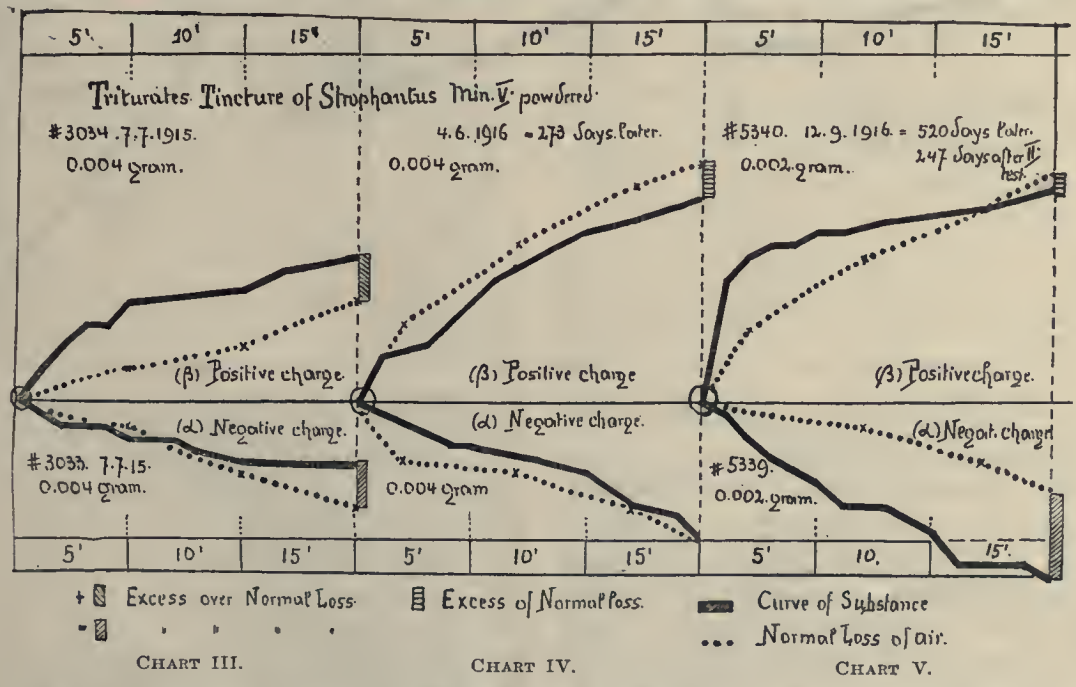

CHART III. CHART IV. CHART V.

Then the sample of the same tablets was stored away, properly protected from light and humidity, and kept at an equal temperature. At the end of 277 days, or more than 9 months later than the first observation recorded, a further examination under identical precautions is represented in chart II, the weight of the tested substance being 0.002 gram or 1/30 grain. Considering the beta curve above the zero line we see quite a steep ascent of the dotted normal loss discharge. The substance curve, however, after a primary steep ascent within the first 10 minutes without any further increase afterward, shows only a slight excess over the normal loss, representing only a minimal activity, or 88.46 per cent. less than 9 months previously. A glance upon the alpha line below the zero line demstance tested, in other words, the smaller the weight of the substance tested, the thinner the layer of the substance, the greater the radiation will be found. This law applied to the present instance the same amount of substance tested—1/15 grain—would yield a still smaller difference from the normal loss.

Chart III demonstrates the readings obtained with 0.004 gram (1/15 grain) of a tablet triturate of tincture of strophanthus, representing a strength of 5 minims. The first test made on July 7, 1915, reveals similar facts, namely the beta curve above the zero line gives for the substances curve a moderate excess radiation over the slowly rising normal loss, which excess stays behind (69 per cent., 23 per cent.) the readings obtained with the 1 minim

CHART VI. CHART VII. CHART VIII.

strates the same course for the normal loss curve as well as for the substance curve.

The difference in the height of the normal loss curves will not escape attention. In the course of my investigations, which extend over a period of 6 years, this difference in the normal loss is dependent upon diurnal and seasonal influences, and partly these readings are influenced by climacteric factors, such as humidity; but especially the actinic strength of the atmosphere will change the readings considerably. We usually are inclined to think that the greater amount of substance tested the greater the effect will be. In my radioscopic tests, however, the constant observation was made that the radiation is inversely proportionate to the amount of subtablet triturate, determined on the same day. For the negatively charged instrument the alpha substance curve remains behind the normal loss. This difference may be attributed to a still persisting inhibition of beta particles which interferes with the continuous discharge of alpha electrons.

In Chart IV we see the result of a test of the same substance, stored away under identical conditions mentioned above, 273 days later. With 0.004 gram (corresponding to 1/15 grain) we notice that the positive normal loss leads over the radiation of the substance curve, a percentual loss amounting to 123.7 per cent as compared with the former reading 273 days previously. The negatively charged instrument shows for the alpha radiation the same

readings for the normal loss and for the substance proper. In other terms, 273 days later the sample tested reveals the absence of beta radiation.

Chart V shows the fontactoscopic readings of the same substance, or 520 days later than the first determination, in the last experiment 0.002 grams, or 1/30 grain, being subjected to the test. The beta radiation sent off by the substance tested after a rapid initial rise within the first ten minutes leads over the normal loss curve; later, however, 15 minutes after the onset of the experiment, the positive normal loss is higher than the electric energy emitted by the substance itself. Compared to the initial readings, the change into negative values in the course of 520 days is quite considerable. For the negatively charged instrument, however, we notice a slow slanting nórmal loss, which remains behind the alpha radiation sent out by the substance itself, with the highest negative excess of electric wave energy at the end of the observation period of 15 minutes. This negatively charged excess compared to the first determination is quite striking, being 75 per cent. higher than 520 days before.

In a comparison of these charts we notice in the one-grain and five-grain samples of triturates of tincture of strophanthus the same tendency to a gradual loss of the radiating qualities. Examined with a positively charged instrument, this radiation appears nearly or completely extinct after nine months. Beyond that time the radiation tested with a negatively charged instrument seems to take the lead.

Having thus determined the loss of radiating energy in digitalis and strophanthus preparations it was of interest to test other cardiac stimulants. A sample is given of fresh specimens of *spartein* sulfate, as seen in charts VI, VII, and VIII. The triturates corresponding to ¼ grain (0.015 gram) were subjected to similar tests as recorded above, the curves being obtained by examining 0.004 gram (1/15 grain) of the powdered substance.

The first curve, seen in chart VI with a positive charge of the fontactoscope, demonstrates a sharp initial rise of the curve, which rise, though less pronounced after the first five minutes of observation, is still in excess at the expiration of 15 minutes over the lower normal loss. This excess, also measured in volts, corresponds to 23.8 volts. For the negative or alpha curve the normal loss is not very different from the beta normal loss, the substance alpha curve, though steep at the onset, reaches a lower level, and after 15 minutes of observation reveals an excess substance loss of 13.1 volts. Considering the scale divisions of the instrument the alpha discharge of the substance is 53.8 per cent., or taking into account the voltage the substance is 44.9 per cent. weaker than the discharge of beta radiation.

Under the identical conditions mentioned, the tablets were stored away, well protected from light, heat, and humidity, and kept at an even temperature until the next test was started 31 days later, July 8, 1915. The results are expressed in chart VII. Notwithstanding the high normal loss on that day, the reason of these variations being still under investigation, the steep curve of beta radiation displayed by the substance remains predominating. At the end of 15 minutes an excess of 37.9 volts over the normal loss was ascertained. A glance upon the alpha radiation curve below the zero line reveals a lesser normal loss which increases after the 7th minute of observation. The substance curve, however, shows a steep fall for the same length of time, which curve is less inclined afterward, but still a negative excess of 23.4 volts remains at the end of the observation. The amount of positive and negative discharge compared with each other shows the negative alpha radiation curve only 25 per cent. less than the beta radiation, by figuring on the scale divisions of the instrument, a comparison of the voltage shows a difference of 38.3 per cent. from the beta radiation. These results, in comparison to those observed 31 days before, reveal a gain of 23.07 per cent., scale divisions, or 37.2 per cent. in volts over the former readings. For the alpha radiation we have a loss of 32.3 per cent., scale divisions, or, figured in volts in the last test, a gain of 78.6 per cent. can be noticed. In other words, in the course of storage the tendency of a leading alpha radiation is manifested which radiation after a certain lapse of time becomes predominant.

Chart VIII illustrates this gradual disintegration representing the readings of the same substance, 0.002 gram (1/30 grain) in powdered form of spartein sulphate being tested—457 days after the first reading, or 426 days after the second.

For the beta curve above the zero line we notice a steep ascent of the normal loss and of the substance curve as well. With an observation period of 15 minutes we notice an excess of the beta radiation over the normal loss, which amounts to 30.4 volts. The alpha radiations of the normal loss and of the substance itself are quite considerable. The substance curve pursues quite a steep curve right from the start, finally to dominate over the normal loss curve, with a result of 60.25 volts in excess Both these curves compared with each other show a gain of 250 per cent., scale divisions, or of 49.5 per cent. in volts, over the beta radiation. Compared to the former readings, obtained from the same substance, we may say that in the course of time the beta radiation may increase for a short while within the first month. After that a gradual loss sets in. The alpha radiation reveals a steady increase, finally being predominant over the beta radiation.

This phenomenon of physical disintegration appears to be general in these investigations in the past 6 years on various pharmaceutical and chemical substances in individual tests lasting from a few minutes to several hours, and in over 6,000 tests including also cardiac stimulants. In the study of radioactive substances we are familiar with the term of the "life time," which expression means the period during which radiation persists. In my investigations I have found that in other medicinal substances also a period of "life time" can be ascertained.

How long does such a period of radiating activity persist is another interesting question under personal investigation; what are the factors at the basis of such a phenomenon? What are the causes of such a decomposition, which may be closely related to the molecular and intramolecular structure? Some of the views regarding that interesting change mentioned in my former publications cannot be fully discussed tonight.

Physical changes relating to the electric radiation being admitted, the question arises as to a possible relation between these physical phenomena and therapeutic efficiency. Personal, clinical, and experimental studies speak in favor of such a relation.

Passing to the third question of this paper, what are the recommendations to be proposed for the preservation of the physical and therapeutic properties of cardiovascular remedies?

1. Whenever possible, use fresh drugs; freshly prepared, they will serve our purpose better for securing help and improvement to the patients. The old and shopworn preparations, after a more or less prolonged existence of oblivion in the drawers or in the form of old solutions, will be called upon in vain to save a patient's life.

2. Proper instruction of the wholesale and retail druggists ought to be encouraged on the subject of this practically important deterioration of chemicals and pharmaceutic preparations. My information, based upon personal experience, as yet incomplete, upon a new field of research, would suggest that the disintegration may be retarded by proper storage, the substances being kept dry in dark containers, protected from light, humidity, and evaporation, at an even temperature. In my experience, fermentative processes in the organic drugs cannot be entirely discarded as possible cause of the changes related above.

In my experimental work I incidentally detected a possibility of increasing the therapeutic efficiency and electric radiation of drugs by a short exposure of various remedies to the passage of electric waves. The practical methods of such a process are still a subject of studies and experimentation, but this much can be said, that the "life period" of the drugs can be raised to several months, and even years. Equally, there seems to exist a possibility of imparting to dead pharmaceutical preparations and compounds new life, and by doing so to restitute and increase pharmacodynamic activity.

PRICE HILL.

Medicolegal Notes.

Expense of Treatment Before Notice to Employer.—A servant of a state hospital did not immediately notify his employer of injuries which he received, but obtained the services of his family physician, and was taken to another hospital. In a proceeding for compensation it was held that the employer was liable for such reasonable medical aid as was received by the servant after notifying the employer as to where he was located and his need for medical aid, where the employer, after such notice, did not offer to furnish it. The more serious question in the case was that of the expenses incurred in the claimed emergency prior to notice. It was held that such an emergency existed, the claimant's family physician finding him suffering from a strangulated femoral hernia, as to warrant the servant in obtaining medical aid without first notifying the employer. The court said that while the rule is sound which requires notice and opportunity to the employer to select the physician and furnish the needed service during the prescribed three weeks before the injured party can secure it at the employer's expense, still, in the many complications which arise in industrial activities it is not an unreasonable or strained construction of the statute, in view of its purpose, to recognize as inferable exceptions in extraordinary cases where the surrounding circumstances and critical condition of the injured person present emergencies or exigencies demanding prompt action, which reasonably warrant the injured party in securing the then needed service at the employer's expense without first giving notice and opportunity to furnish or offer the same. Such cases are, of course, distinctly exceptional, and consequently rare. Where such exception is claimed, the question of a pressing necessity demanding and excusing prompt action before reasonable time for notice and opportunity thereafter for the employer to act becomes primarily an issue of fact.—Gage v. Board of Control, Michigan Supreme Court, 172 N. W. 536.

Good Will of Physician's X-Ray Practice.—The business of a physician who specialized in *x*-ray pictures as an aid to physicians, and who had a high reputation in his specialized field, and had made many improvements and inventions in the art, is held to have no "good will" transferable after his death, which could be subject to transfer tax, since any good will was personal to the physician and not to the place of business or to any trade-mark or trade-name, especially where the business was not afterwards conducted under his name. The question whether the good will of the practice and business of a man who has attained eminence in his profession has, upon his death, a value that is capable of ascertainment or computation, does not seem to have been decided in the reported cases. It has been held that a doctor may sell the good will of his business and that the courts will recognize the right of the purchaser to the good will. But there seems to be a distinction between the business sold by a doctor during his lifetime and the value of that business after his death. If sold during his lifetime, he could introduce the purchaser to his patients and friends as a prudent and reliable physician, and such introduction would immediately give the purchaser a reputation and standing which otherwise might require years to establish. As the profitable business conducted by the deceased in the present case was the result of his superior knowledge and skill, and the business was not conducted under his name after his death, it was held there was no good will subject to a transfer tax.—*In re* Caldwell's Estate, 176 N. Y. Supp. 425.

Cause of Death—Accident Hastening Disease.—A night watchman at a foundry went to work as usual on April 18, 1917. The following morning he was discovered at the foundry in a state of collapse He developed pneumonia and peritonitis, and after a few days died. His dependent claimed, under the Maine Workmen's Compensation Act, that his pneumonia was traumatic, and that the injury causing it was due to an accident sustained by the deceased while alone at the foundry on the night of the 18th. When he was discovered, on the morning of the 19th, he said, "I got hurt," and then or afterward indicated where he was hurt. The employer claimed that the death was not due to injury, that when deceased began work on the 18th he was "coming down" with pneumonia. The court held that this, if true, was not decisive. Evidence that an existing disorder reaches the point of disablement during employment, of course, does not prove accidental or other injury arising out of such employment. It is sufficient, however (assuming other elements proved), if by weakening resistance or otherwise an accident so influences the progress of an existing disease as to cause death or disablement. Was the disease caused by, or was its fatal result due to trauma? If the Supreme Court had been the trier of the facts, it indicated it might have decided that issue in favor of the defendant. But the commissioner found the issue for the plaintiff. There was some evidence that on the deceased's body a mark or marks were observed which turned black when blood poisoning set in. There was some medical testimony to the effect that the symptoms were more consistent with traumatic pneumonia than with illness otherwise caused. The spontaneous exclamation of the suffering man, "I got hurt," clearly admissible for this purpose, showed that he sensed the shock of a hurt rather than the prostration of illness. It was held that it could not be reasonably said that there was no evidence that the deceased's illness was traumatic, and the award was affirmed.—Mailman v. Record Foundry etc. Co. (Me.), 106 Atl. 606.

HYPODERMIC INJECTIONS OF PURGATIVE DRUGS.

FOR some time past attempts have been essayed to exhibit purgative drugs by the hypodermic route. Some have experimented with purgative salts in particular, others with extracts and the active principles of plants, as well as purgative roots. Of late some success has been derived from a synthetic purge, phenolphthalein and its derivative, sodophthalyl. Many physiologists have endeavored to ascertain the action of injectable purgatives when given subcutaneously, from which has resulted a large number of special procedures which have led to radioscopy, radiography, and the method of intestinal perfusion.

Braillon (Thèse de Paris, 1913) has experimented with rabbits and dogs with the view more particularly of testing the toxicity of those purgatives which can be given subcutaneously. He employed sodium citrate and sulphate, magnesium sulphate, infusions of cascara, senna, and rhubarb, the bark of black alder in infusion and maceration, aloes in a tepid solution, and, lastly, phenolphthalein.

Injections of sodium sulphate are painful, causing an induration at the site of the infection which may result in sloughing. This salt produced frequent and abundant stools but never liquid ones. The citrate is extremely painful when injected subcutaneously and should be rejected in practice regardless of its excellent results as a purge. Magnesium sulphate (20 per cent. solution) gave no result, but rather constipated the animals and occasionally produced a considerable reduction in the weight of the feces. The infusions of senna, rhubarb, and cascara given subcutaneously produced in the rabbit stools softer than usual while at the same time the weight of the feces was increased. The same results were obtained with the bark of black alder. A 4 per cent. solution of aloes was toxic for the rabbit, but dogs supported it well and the purgative results were distinct. In rabbits phenolphthalein did not produce liquid stools but an increase of weight of and a softer consistency of the dejections. In a dog with an intestinal fistula a distinct purgative effect was noted, as well as an increase of the intestinal secretion.

In their experiments with intestinal perfusion, Carnot and R. Glénard used the same drugs as Braillon. They found that sodium sulphate increased or exaggerated peristalsis but did not appear to influence greatly the secretion. Sodium citrate paralysed the intestine, which became filled with a large quantity of transuded fluid, which, because the gut could not expell it, ruptured the intestine. Magnesium sulphate arrested intestinal peristalsis and checked the evacuation of the stools. Senna was found to exaggerate peristalsis and the intestinal output and it also had a very distinct lymphagogue action. The bark of black alder possessed the same properties. Aloes energetically increased the movements of the gut and produced a vasodilatation of the mesenteric vessels, while the intestinal output appeared to be slightly increased. Phenolphthalein exaggerated peristalsis and increased the intestinal secretion, but the contractions were not so energetic as those obtained with aloes, senna, and especially sodium sulphate.

Clinical observation leads us to believe that subcutaneous or intravenous administration of purgatives is possible, and all the drugs above mentioned have given clinical results. Injections of sodium sulphate or citrate and the solution of aloes are to be rejected, either because of the pain produced or by reason of their toxicity.

The question of subcutaneous injections of purgatives is sufficiently interesting, as well as important, for continued research, because in practice this method of exhibition unquestionably has important therapeutic indications where prompt purgation is required, as in coma, incoercible vomiting, etc.

THE STUDY OF CRIMINOLOGY.

THE science of criminology has increased greatly since the days of Lombroso and Nordau. A new view is now taken of the subject and the criminal or the potential criminal is not judged exclusively by physical characteristics or abnormalities.

Dr. Charles Goring, of the English prison service at Manchester, was one of the first to regard the matter from this novel aspect, and for several years was engaged on a great statistical study of criminals from almost every conceivable angle. Goring died last May from pneumonia at his post in Manchester and his remarkable work on criminology has been issued in an abridged edition by an English Government Department. This edition is also notable for an introduction by Professor Karl Pearson. It may be stated that Goring made the first attempt in Great Britain or any other country to reach results in criminology by the statistical presentation and analysis of facts. He was responsible for the detailed examination of 3,000 convicts, making 15,000 observations himself. Incidentally by the cold logic of facts, he appears to have destroyed for all time the long held theory that there is a definite criminal type. The Bill Sykes type of burglar, as limned by Dickens, with low

beetling brow, with large ears, coarse jaw, and general mien of truculence and ferocity, is not really synonymous with the burglar type. Indeed, there is no burglar type, and the successful house breaker and safe cracker is perhaps most frequently an unassuming, inoffensive looking little man, who resembles a church deacon or a college professor. To rise to great heights in the burglary profession, it is not well to bear on one's person the earmarks of the burglar of fiction. In the same way, as Goring points out, it is foolish to distrust a woman with pale face, red hair, or green eyes. With reference to the size of the head or frontal development as a criterion of criminal propensities, Goring has shown that such a belief is untenable. He measured the heads of 800 criminals and reconstructed the typical criminal head. He then compared this head with the head obtained from the examination of 118 men of the Royal Engineers. The difference was found to be slight.

Karl Pearson sums up the results of the Manchester man's investigations very aptly when he says, "The criminal is not a random sample of the population, either physically or mentally. He is rather a sample of the less fit moiety of it."

The moral to be extracted from Goring's studies is the large part that mental defect plays in the drama of crime, and the fact that a large proportion of the mentally defective are not defective at all from the intellectual side. Pearson says that, to use a biological expression, they have never possessed, and never will possess, the instinct of the gregarious animal, the instinct which compels them to observe the rules of the pack. They feel no social nor moral responsibility, no instinct of the herd, without which any society, either of man or of beast, must cease to exist.

After emphasizing that the need of the moment is apparently the fuller study of mental defect, Pearson goes on to show that in this study the criminologists of America are ahead of those of Great Britain. They are putting into practice and developing the facts that Goring spent his life in accumulating. It has been recognized in America that the criminal in most cases is a mentally sick man, suffering from a more obscure disease and one more difficult to treat successfully than a disease of a physical nature. For their own good and for the protection of the public, it is necessary to isolate them, but prisons and reformatories should be looked upon as asylums for the mentally defective and as laboratories for the study of criminology, and not merely as penal establishments.

ORAL INFECTION AND MENTAL DISEASE.

Infection of various kinds is not infrequently associated with mental disturbances, generally temporary in nature. But it has not been generally recognized that more chronic forms of mental disturbance, actual mental disease or some of the forms of insanity, might also be due to infection and, further, might be successfully treated by the removal or cure of that infection. Evidence in support of this latter statement is submitted by Henry A. Cotton in a recent paper (*Jour. Dental Research*, 1919, i, 269). The author, in brief, submits the histories of a number of patients who were admitted to the New Jersey State Hospital and in whose cases the diagnoses of various types of mental disease were confirmed by clinical study. After the failure of other forms of treatment, the removal of teeth with infected roots and of infected tonsils, and the treatment of gastric conditions apparently associated with local infection, was followed by remarkable improvement and in many instances the patients recovered as permanently as could be determined by observation for from one to three years after discharge. These statements are startling and yet on mature consideration need not remain so. It is quite apparent that many instances of mental disease are manifestations of some form of toxemia and it is not essentially difficult to reason that if the cause of a toxemia be removed its effects will cease. The clinical and therapeutic aspects of this report may be accepted as a noteworthy contribution whose exact value will naturally be determined by other investigations. The bacteriological theories proposed are much more difficult of acceptance. The author rightly says that "members of the medical profession are skeptical as to the validity of the theories discussed." That this skepticism is justified must be acknowledged when one theory claims the identity of the Gram-negative "Connellan-King" diplococcus and the Gram-positive *Streptococcus viridans*. The author also places much more dependence upon the complement fixation test for the non-hemolytic streptococci than is usually done by laboratory men. It seems to us a little extreme to say "The use of this test would remove all doubt as to the advisability or necessity of extracting impacted molars, when the patient is apparently healthy and the infection has not reached dangerous proportions. When the test is positive the impacted molars should be extracted." It may be that with greater perfection in the technique, the complement fixation test will command greater confidence than it has at present, but it is well-known that in many types of known infection the results are apt to be unsatisfactory. Further the author describes achylia gastrica as he has observed it, as due "to the presence of streptococci in the stomach wall and in the peptic glands, where they interfere with the secretion of HCl." This statement also will require much evidence to support it. But in spite of all the criticisms which we may make of his theory, the results of his practice are apparently remarkably satisfactory and after all that is the essential thing. If he can pull teeth and enucleate tonsils and thereby restore the mentally diseased, he will accomplish much and will deserve much honor.

An Echo of Influenza.

Echoes of the pandemic as compiled from official records appear to be coming in from all parts of the world, and will doubtless lead to a revision of

the history of this experience as we now understand it. In a recent Paris thesis on Grippe in the St. Antoine Hospital during 1918-19, by Barbier-Jacob, an abstract of which occurs in the *Journal de médecine et de chirurgie pratiques* (October 10, 1919, xc, 19), it is stated plainly that the disease had visited the institution in April, or at least a month before it first broke out in Madrid, and the malady has never died out there, for cases have occurred continuously ever since. The stages of its sojourn are not given and we do not know how virulent were the early cases. The general statement is made that the mortality of the grave pulmonary cases was around 50 per cent. and that these cases suggested the possibility of the lung plague. In certain cases the signs of adrenal insufficiency were marked, and the collapse, algidity, enteric symptoms, etc., suggested cholera, and also other disease pictures, such as dysentery. Siredey, the senior physician, employed a variety of remedies as camphorated oil, strychnine, adrenalin, caffeine, wet cups and venesection, abscess produced with turpentine, and intravenous injections of colloidal silver. The benefits of the treatment were apparent, for the cases represented the very worst in Paris, and the total mortality of 19 per cent. is regarded as a triumph. The most striking feature of the reports is the early and long-continued incidence. This is to be explained with great difficulty unless we assume that it illustrates the impossibility of distinguishing between the pandemic and influenza nostras.

Helium.

Although helium has no direct application to the practice of medicine it is a product of radioactivity and of value in aerostatics, while it is now prepared in large quantities from petroleum gas, especially from the newly discovered supply of the Southwestern States. According to a writer in the *Gazette hebdomadaire des sciences médicales de Bordeaux* for September 21, this gas was first discovered in the solar spectrum by the Frenchman Janssen in 1868. We learned nothing more about it until Ramsay discovered its presence on our own planet. While it is formed in the disintegration of radium it has natural sources in the gas produced in warm springs and natural illuminating gas which occurs in petroleum fields. Many years ago a French business firm extracted 200 liters of it from the thermal springs at Bourbon-Lancy. However, in recent years it has been found in such quantities in the natural gas of Kansas and Texas that the United States will supply the growing demand for it as a substitute for the more dangerous hydrogen in balloon gases, it being both light and incombustible. The oil wells of Petrolia, Texas, alone yield daily 700,000 cubic meters. There are several methods and processes for obtaining it, and the price per cubic meter has been reduced from 20 francs to 4 or 5. Just before the armistice was signed it is said that a large shipment of several thousand cubic meters was about to be made to the American army in France by the United States Government. For the purpose of inflating aerostats it is claimed that this gas is reasonably cheap as well as effective and safe.

News of the Week.

Insane Patients Missing in Hospital Fire.—Eight patients of the Connecticut Hospital for the Insane at Middletown are believed to have lost their lives in the fire which completely destroyed one of the frame buildings of the hospital group on the night of December 22. Of the fifty-three patients in the building only forty-five had been accounted for at midnight. The patients were all cases of the milder types of insanity. When the flames were discovered they assisted the "bucket brigade" in rescuing clothing and furniture. The missing patients are believed to have been burned to death when the interior of the building collapsed.

Vital Statistics for New York State.—According to the statement issued by State Health Commissioner Hermann M. Biggs, while the birth rate per thousand inhabitants for the State as a whole was slightly higher in October than that during the summer months, it was lower than for the year 1918, and was lower than the average five-year rate for any month during the period of 1913-1917. The general death rate of 10.3 per thousand inhabitants for the State as a whole for October was identical with that for September, and was a fraction lower than that for June, July, and August. The death rates for the five months from June to October, inclusive, of 1919, were the lowest monthly death rates ever recorded for the entire State. The infant mortality rate of 70 for October was 20 points lower than the average rate for that month during the five years of 1913-1917. The 49 deaths from typhoid fever during October were less than half the average for that month during the 1913-1917 period, and less by 8 than the number for September of 1919. Diphtheria showed a slightly higher mortality rate in October than the five-year average. Deaths from automobile accidents increased from 79 in September to 128 in October.

The American Congress on Internal Medicine, in conjunction with the American College of Physicians, will meet in Chicago February 23 to 28, 1920. The sessions will comprise daily clinical and laboratory demonstrations in many of the leading hospitals and teaching institutions of Chicago, and special evening meetings. Dr. Frank Smithies, 1002 North Dearborn Street, Chicago, is the Secretary-General.

Nearly Two Million Dollars in Charitable Christmas Gifts.—According to press notices, Mayor James Couzens of Detroit, Mich., distributed approximately two million dollars, chiefly to institutions for the care of crippled children and orphans, all of the city of Detroit. The sum was apportioned as follows: Annex for Michigan Hospital School for Crippled Children, $450,000; endowment fund for school, $650,000; total for school, $1,100,000. Nurses' Home, Harper Hospital, $650,000; Children's Free Hospital, $125,000; St. Vincent's Orphan Asylum, $75,000. These sums total $1,950,000.

New Medical Swindle.—The Newark, N. J., police have asked the authorities of other cities to look for a suave, tall man, wearing a fur overcoat, who posed as "consultant" in the case of a patient of a Newark physician, collecting a three-dollar fee for his "services." Soon after the physician left

the home of the patient, the "consultant" arrived, expressed surprise that the doctor did not wait for him, explained his mission to the patient's husband, and proceeded to make his "examination" of the patient. With dignified solemnity and a muttered grave prognosis he proceeded to "make notes" on the case, after which he collected and departed.

New Hospital Ship Launched.—The United States Hospital Ship *Relief* was launched at the Philadelphia Navy Yard, December 23. Mrs. William C. Braisted, wife of the Surgeon General of the Navy, was the sponsor. The ship is of 10,000 tons displacement, and is 483 feet long, with a speed of 16 knots. Congress appropriated $3,250,000 for this ship, which is said to be the first of its kind ever constructed. The work was begun in 1917, but was abandoned during the war. The vessel has a capacity of 500 beds, with complete operating rooms and field hospital equipment. She is divided into wards for the segregation of various diseases. She will carry, in addition to the crew, a complete medical staff of officers, nurses, and hospital corps men.

Return of Sick Soldiers to Civil Life Opposed.—National Headquarters of the American Legion at Indianapolis opposes the recent War Department order calling for the release to civil life of service men who have been under treatment in hospitals for more than twelve months. Officers and enlisted men confined in hospitals receive full pay, but when returned to civil life tuberculous and other incurables will receive but $6 to $30 a month. The Legion wants such action by the War Department postponed until provision will have been made for these men by Congressional legislation. The War Department order would throw on public charity the responsibility of caring for a large number of these sick.

Trained Nurses Developing the Strike Germ.—The five hundred New York and Brooklyn nurses who constitute the Trained Nurses' Association, Local 16,461, American Federation of Labor, have begun a Campaign to include in its membership the rest of the 3,500 nurses employed in this city, and to secure for all an eight-hour workday. Circulars setting forth the alleged grievances of the nurses have been distributed. As recently noted, the pay of nurses doing private work has already been advanced from $5 to $6 a day.

Shell-Shock Patient Shoots Doctor.—Dr. John F. Rooney of the Public Health Service was shot three times, December 20, by Walter S. Holbert, a former soldier and patient at Providence Hospital, Washington, D. C., where Dr. Rooney had attended him. When captured the ex-service man declared his act was prompted by the belief that the doctor had not given him the attention his condition warranted. The soldier was wounded in the Argonne fighting.

Changes in Sanitary Code.—A number of changes, effective January 1, 1920, have been made in the Sanitary Code of the City of New York as it affects the removal of unidentified bodies to and from the morgue. The changes are the outcome of abuses of existing laws practised by certain undertakers, culminating in a recent glaring instance, in which a woman, who died of injuries received when she was struck by a taxicab, was hurriedly and mysteriously buried within thirty hours after the accident. Investigation by the woman's daughter revealed facts which caused the action by the Health Department.

Physicians Who Fail to Report Communicable Diseases to be Prosecuted.—The intention on the part of the Department of Health of the City of New York to enforce the sections of the Sanitary Code which make compulsory the reporting of communicable diseases by both physicians and institutions is evidenced in a statement issued in the *Weekly Bulletin*, under date of December 20. When the officers of the Department of Health, according to the statement, ascertain that the required information has been withheld by physicians, dispensaries or hospitals, it becomes their unpleasant but imperative duty to bring such delinquency to the notice of the Commissioner. The latter has no alternative but to make a thorough inquiry, and, if the facts warrant such procedure, to resort to legal action to enforce compliance with the regulations.

Medical Journals Merge. — The *Medical Herald and Electro-Therapist* of Kansas City makes the following announcement: Several years ago, the *Medical Herald* absorbed the *Kansas City Medical Index* and *The Lancet*. About the same time, the *Medical Fortnightly* of St. Louis took over the *Laboratory News*, which in turn had several years previously succeeded the *General Practitioner* and *The Clinique*. So in line with the spirit of the times, on January 1, the *Medical Herald* and the *Medical Fortnightly* will join forces, and thereafter will be issued as one journal, thus combining seven publications in the *Medical Herald and Electro-Therapist*.

Civil Service Examinations.—The New York State Civil Service Commission announces examinations to be held January 24, 1920. On the list of positions and requirements are the following:

Bacteriologist, Rockland County Tuberculosis Hospital. Salary $75 a month. The duties required are as follows: Uranalysis, blood, sputum, and stool examinations, examinations of stomach contents, complement fixation, preparation of vaccines, culture work including the preparation of culture media, clinical as well as bacteriological analysis of water and milk. A general knowledge of histopathological technique is also required. Subjects of examination: Written examination relating to the duties of the position, relative weight 1; education, training, experience, and personal qualifications, relative weight 1.

Bacteriologist-Pathologist, State Department of Health. $2500 to $3000. Age limits 25 to 45 years; preferred ages 30 to 40 years. Candidates should have a degree in medicine and a thorough knowledge of the principles of bacteriology, pathology, and immunity. They should have had considerable experience in both bacteriology and pathology. They will be rated on education, training, experience, and personal qualifications. They may be required to make a written statement of their conception of the duties of the position. Inquiry may be made as to their character and ability, and all statements of experience are subject to verification. An interview may be required. Open to non-residents and non-citizens.

Obituary Notes.—Dr. GEORGE E. CHAMBERLAIN,

formerly of Boston and later of South Newbury, Vt., died after an operation, December 16. He had been in ill-health for some years, and was not in active practice. He was graduated from Dartmouth Medical School in 1896.

Dr. JOSEPH J. CRONIN of Boston, Mass., died at the Peter Brent Brigham Hospital, November 30. Death was caused by blood poisoning following infection of the left hand during an operation. Dr. Cronin was graduated from Jefferson Medical College in 1885.

Dr. CHARLES ALBERT FOLSOM died at his home in Epping, N. H., December 12, at the age of 45. After graduating from Dartmouth Medical School, in 1902, Dr. Folsom practised for fourteen years at Manchester, N. H., retiring a year ago. He was a member of the New Hampshire State Medical Society, the New Hampshire Surgical Society, and other organizations.

Dr. J. H. GIFFORD of Fall River, Mass., died December 15, at the age of 61. He was graduated from Harvard Medical School in 1884. He was a member of the Massachusetts State Medical Society, and was associate medical examiner in his district.

Dr. GIUSEPPE DALLA-CHIARA of New York City died at the Presbyterian Hospital December 15 of cancer of the lungs and bronchial tubes. Dr. Dalla-Chiara, who was 53 years of age, was born in Italy, and practised medicine in Rome and Milan. He had been practising in this city for five years.

Dr. NELSON GREGORY HALL died December 15 in the house in which he was born, in 1833, at Nut Plains, Conn. He was graduated from Yale Medical School in the class of 1861, of which he was "the last leaf."

Obituary.

SIR WILLIAM OSLER, M.D., LL.D., F.R.C.P.,

OXFORD, ENGLAND.

SIR WILLIAM OSLER, Bart., Regius Professor of Medicine in the University of Oxford, died at his home in Norham Gardens, Oxford, December 29, in his seventieth year. He became ill with pneumonia in November. Pleurisy developed, necessitating thoracentesis, but he was thought to be making favorable progress. Three days before his death he cabled Christmas greetings to friends at Johns Hopkins Hospital, telling them he was making a good fight.

Dr. Osler was born in Tecumseh, Ontario, and received his preliminary education at Trinity College School, Trinity College, Toronto, and at medical department of McGill University, Montreal, Toronto University. He was graduated from the in 1872, receiving a special prize for his graduating thesis on pathological anatomy. After two years spent in study abroad he returned to Montreal. In 1874 he become professor of the institute of medicine, McGill University, holding this position until 1884, when he became professor of clinical medicine in the University of Pennsylvania, Philadelphia. Five years later he became identified with Johns Hopkins University, Baltimore, as professor of the principles and practice of medicine. He held this position until 1905, when he became regius professor of medicine at Oxford.

Dr. Osler was the recipient of many honors conferred by universities and scientific societies. In 1883, while he was still at McGill University, he was made a fellow of the Royal Society of Physicians. In 1895 he received the honorary degree of Doctor of Laws from McGill University; in 1898 from the University of Aberdeen, and the University of Edinburgh; in 1899 from the University of Toronto; in 1901 from Yale University; in 1904 from Harvard University, and in 1905 from Johns Hopkins University. The degree of Doctor of Civil Law was conferred by Trinity University, Toronto, in 1902, and by the University of Durham in 1913. He received the degree of Doctor of Science from Oxford University in 1904, Liverpool University in 1910, and the University of Dublin in 1912. In 1911 he was created a baronet of the United Kingdom by King George V.

Through his teaching Dr. Osler became known and loved by hundreds of students and physicians in Canada, the United States, and Great Britain, and through his writings he became the honored guide in the science of diagnosis of thousands more. He was a voluminous contributor to medical literature, as the 730 titles listed under his name attest. His "Principles and Practice of Medicine," and "Modern Medicine," of which he was coeditor. are his chief works.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, Dec. 12, 1919.

Increase of the Fees of Medical Men.—The Council of the British Medical Association has recommended an increase in doctors' fees to the extent of 50 per cent over pre-war rates. The fact has been made public recently by Dr. G. C. Anderson, the deputy medical secretary of the association. Dr. Anderson said it was impossible to give any idea of what minimum charges were in different districts. The size of the fee depended entirely upon the individual practitioner, and varied in different neighborhoods. The sanctioned increase, however, referred to every member of the profession.

Appeals for London Hospitals.—In the course of a week dinners have been given under distinguished patronage to solicit pecuniary aid for three large London hospitals. The first of these dinners was presided over by the Prince of Wales, and was the first function he attended after his return from America. It was to help in raising $1,000,000 required to clear Middlesex Hospital from debt. The second dinner was held the following evening and was also presided over by the Prince of Wales, and was for the purpose of getting together a large sum to free the Great Northern Hospital from debt. The third dinner, which took place on the same evening, was under the chairmanship of Prince Arthur of Connaught, and had as its object the placing of King's College Hospital on a satisfactory financial basis. Hospitals in every part of Great Britain are laboring under severe pecuniary stress,

partly due to the effects of the war and partly owing to the fact that the working classes and poor of the country are beginning to appreciate the value and advantages of hospital treatment. The consequence is that the accommodation is woefully inadequate and that there are immensely long waiting lists. The hospital question is now acknowledged to be pressing and serious, and one that calls for immediate attention. It cannot be said that the voluntary system has failed, but it map be said that it is unable to cope with present conditions. It requires reconstruction and coordination and better organization. It does not seem at all likely that we are on the eve or even at all near a state controlled system. The Ministry of Health will not dream of adding to its already overburdened program, and the present mode of control, with certain greatly needed forms, will doubtless continue.

The Administration of Anesthetics by Unqualified Persons.—Owing to the lack of skilled and qualified anesthetists during the war, anesthetics were more or less frequently administered by unqualified persons. Indeed, if my memory serves me well, it was suggested in the United States that nurses should be trained to give anesthetics. However, in Great Britain the practice is frowned upon severely, and Dr. F. J. Waldo, Coroner for the City of London, is initiating a campaign against such a procedure. There have been one or two fatalities of late in cases in which the anesthetic was given by an unqualified individual. Dr. Waldo in 1908 contributed articles to the *Lancet* and *Medical Press* in which he asserted that available data as to deaths during anesthesia were so imperfect as to be useless for the purposes of formal investigation. It therefore followed that the so-called statistics and published figures regarding that class of mortality were worthless and misleading. Dr. Waldo made certain recommendations and the matter was brought to the attention of the Home Office, and a Departmental Committee was appointed in December, 1908. The committee reported in March, 1910, as follows: (1) No general respirable anesthetic should be administered by any person who is not a registered practitioner or dental practitioner. (2) Registered dentists should be confined to the use of nitrous oxide gas for dental operations, and should not employ the general respirable anesthetics of the longer duration. (3) Intraspinal anesthesia should be practised only by registered medical practitioners. (4) In the case of any death under an anesthetic in a hospital or other similar public institution there should be a scientific investigation into the actual cause of death conducted by the authorities of the institution. (5) A small scientific committee on anesthetics should be instituted under the authority of the Home Office. The report and recommendations were published nine years ago, and nothing has been done. It is an important matter, and it is in the interest of all concerned that the question should be reviewed.

Sale of Canadian Hospital.—Brig.-Gen. R. Manley Sims, C.M.G., D.S.O., Agent-General for Ontario, has sold on behalf of his Government the Ontario Military Hospital at Orpington to the British Ministry of Pensions for $400,000. This hospital, which has accommodation for 2000 patients, was the largest Canadian military hospital in England, and during the war it performed splendid work on behalf of the wounded. The hospital was built and equipped by the Government of Ontario. The buildings, with all the valuable equipment of a complete hospital, have been handed over to the Ministry of Pensions, who intend to use it for the care and treatment of convalescents and disabled soldiers transferred to the Ministry by the War Office.

Health of the British Forces.—The Chadwick trustees have resolved, under the powers conferred upon them by the scheme which they administer, to award next year a Chadwick gold medal and a prize of $500 to the naval and military officer respectively in the British service who during the past five years of war shall be deemed to have distinguished himself most in promoting the health of the men in the navy and army. The nomination to the trustees for such presentation will, as provided by the trust, be made by the directors-general of the naval and military medical services respectively.

Congress of the British Royal Institute of Public Health to be Held in Brussels in 1920.—The annual meetings of the Royal Institute of Public Health, which were in abeyance during the war, will be resumed in 1920. An invitation has been received from the Burgomaster of Brussels on behalf of that city, and from the Rectors of the University of Belgium for the next congress to be held in Brussels. The invitation has been accepted, and the meetings will take place from Thursday, May 20, to May 24, inclusive.

LETTER FROM PARIS.

(From Our Own Correspondent.)

PARIS, December 1, 1919.

Modified Theories of the Treatment of Infections.—The latest work done in France in anti-infectious therapeutics and the discussions which have taken place in the medical societies on this subject, show that the various treatments advised of late possess a modus operandi about identical but that this modus operandi is quite different from what we had thought theoretically. The belief in the specificity of the various sera has, for this reason, received a severe shock. That it does exist is not questioned, but it is not looked upon as the primordial element of their efficiency. Likewise, it is no longer certain that the colloid metals, which have been so highly vaunted, act by the virtues which the metals themselves possess, or at least their specificity is no longer considered absolute.

Even the subcutaneous injections of turpentine given to promote the development of a fixation abscess are at present understood in a different light. In fact, it would seem that in all these modern therapeutic measures the principal element of success resides in the reactions provoked by the introduction of foreign albumins into the organism in the case of sera and in other cases simply the introduction of foreign matter. These reactions are considerably increased and provoked at the proper time; otherwise they are exactly the same as those which arise in the organism when an undesirable pathogenic guest enters it. Even infection gives rise to this kind of defense and

modern treatment reinforces it. This is why it seems possible to establish an antiinfectious treatment which does not take the nature of the infection much into account and, therefore, to resort indifferently to colloidal metals in influenza or puerperal infection, to utilize fixation abscesses in pneumonia and in all sorts of other morbid processes. Finally, streptococcic septicemia can be treated with antidiphtheritic serum when nothing else can be had.

Nevertheless, the very principle of the defense of the organism, be it spontaneous or artificially provoked, is invariably the same or at least constantly acts as the principal element by the formation of an imposing number of leucocytes which here play the famous part of gendarmes. Now, there is an old, simple and more practical method —and less brutal—for giving rise to this activity of the lymphoid tissue whose most important ultimate result is the development of the phagocytes. I refer to the fixation abscess, a method devised by Fochier, of Lyons, some thirty or more years ago, and whose excellent results in pneumonia were revealed to your correspondent when a student by that great master of clinical medicine, the late Prof. Revilliod, of Geneva. Fochier employed fixation abscess in puerperal infection, Revilliod resorted to it in medical infections, especially pneumonia. Having made this digression in medical history, let me say that fixation abscesses have their disadvantages, injections of serum are painful and cannot be indiscriminately given, the injections of colloidal metals are frequently followed by intense and brutal reactions which cannot be regarded with indifference and which are encountered in all the above mentioned therapeutic measures. Nevertheless, they have come to stay and when proper prudence is exercised in their exhibition ill results will be few.

Intolerance of Infants for Human Milk.—Some very good work has been done at Lyons by Prof. Weill in the treatment of intolerance of infants for human milk, a rare occurrence, it is true, but which is nevertheless encountered. Weill has also employed his treatment to infants brought up on either mixed or artificial feeding. The method consists of injecting subcutaneously maternal milk in the abdominal parietes in doses of from five to fifteen cubic centimeters. The milk must be collected with all due asepsis and may or may not be sterilized at 110° C. The child's temperature is unaffected by the injection, while locally there may be a transient edema.

Injections of cow's milk cause a rise in temperature lasting for forty-eight hours, but they are without danger, as has been shown by a sufficient number of clinical experiments. When it is necessary to resort to frequently repeated injections it is well to give the second and third injections in fractional doses, as is done in repeated seric treatment. The intensity of the local reactions may be foreseen by resorting to the intradermic test, which consists in introducing one-twentieth of a cubic centimeter of the milk being given to the infant into the deep strata of the dermis. A rather distinct reaction rapidly takes place lasting from one to two days, but will be absent in infants with a good digestion.

The disturbances presented by the infants treated by Prof. Weill consisted of vomiting soon after nursing. The vomiting was often preceded by very severe pain almost as soon as the child began to nurse, causing crying and insomnia. Now, in the cases treated these disturbances disappeared permanently, a single injection being often enough for obtaining this result. Weill is of the opinion that the treatment is a sort of vaccination against toxic substances which form in the stomach when the milk comes in contact with the gastric mucosa.

The Laennec Centennial.—A few weeks ago was the one hundredth anniversary of the publication of Laennec's immortal work: "Traité de l'auscultation médiate." Some speeches were made at the foot of the statue of the illustrious clinician, at Quimper, and a commemorative slab was placed on the house at Polaré, where he died.

Two men created the clinical school of France, namely, Corvisart and Laennec. In reality, the former only had the intuition, the general idea, so that his principal merit was unquestionably to have been the teacher of the latter. Corvisart was a physician of the highest type and justice has not been done him, but to bring medicine up to the point it reached, the pathological work and teachings of Laennec were necessary. Clinical teaching he had as physician to the Charité Hospital, and here he acquired a high degree of skill in clinical work which resulted in the publication of his book on auscultation, which did away with all the then existing false notions on diseases of the thoracic viscera.

A gift of unusual observation and analysis was necessary in order to classify the sounds heard and to interpret their significance, as well as to make out the bonds uniting the symptom with the lesion; to group together these scattered elements, to condense them into a universally applicable method, was accomplished by Laennec. His great glory is to have founded method in medicine upon the ruins of systems, and it is still the light of Laennec's work a hundred years ago that at present guides the practice of medicine in France.

7. The Relation of Malaria to Pregnancy.—Bernard Kaufman holds that the presence of malaria during pregnancy, either early or late, need cause no great alarm so long as its presence is recognized and steps are taken to combat it. If allowed to remain untreated, however, it will sooner or later lead to abortion or miscarriage. The occurrence of pregnancy seems to relight into activity latent or chronic malaria which had remained dormant for long periods. This seems to be borne out by the total disregard to the seasonal incidence with which active symptoms of malarial infection develop in pregnancy. Whether discovered early or late in pregnancy, routine treatment with quinine is necessary to prevent abortion or miscarriage. After delivery it is necessary to prevent reinvasion; to hasten involution of the uterus and thus prevent postpartum hemorrhage and infections; to aid in permitting perineal wounds to heal better; to preserve normal milk conditions for the infant; to rule out malaria in the presence of other infections, as a therapeutic test; and to maintain normal mental equilibrium of the mother.

1. Typhoid Fever in the American Army During the World War.—Frederick F. Russell reviews and tabulates the statistics for typhoid and paratyphoid fevers for the period of the great war. From this study he holds that antityphoid vaccination, carried out as it was by a personnel which had not been carefully trained in its administration, gave a high degree of protection to our forces under the conditions of hurried mobilization and of warfare, and reduced the rate, not only below the rates for previous wars, but also below the rate found in civil life in some of the older states where the entire population is protected by all the sanitary measures of modern life.

9. Complement Fixation Test for Tuberclosis.—Pritchard and Roderick studied a series of 466 cases, in which the final diagnosis was: pulmonary tuberculosis, including suspects, 220; extrapulmonary tuberculosis, 13; nontuberculous, 233. All patients were first given a general examination by the internist who referred them to the writers. The clinical chest study consisted of a careful history, a physical and fluoroscopic examination with an interpretation of stereoscopic plates of the chest, and three sputum tests as well as a three days' pulse and temperature observation. The serologic study consisted of a Wasserman test with both cholesterin and acetone antigens, and a complement fixation test with two antigens for tuberculosis. The work was finished separately and charted. The physical findings were recorded before the roentgenographic interpretations were made. In no case did the laboratory have an information regarding the patient. The complement fixation was estimated in terms of +, ++, +++ and ++++, but all cases below +++ were considered as negative. With few exceptions, the blood was collected before breakfast. The collecting of a specimen after a meal will often give "fatty serum," which may bring about unreliable results. Fresh serum was used in nearly all the tests. The antigen used was the bacterial emulsion of Miller. Practically the same results were given by antigen obtained from a manufacturer and that made in the writers' laboratory. For complement purposes anesthetized guinea-pig were bled from the heart. The serums of three guinea-pigs were pooled and used in all cases within the first sixteen hours. Rabbit antisheep amboceptor, made and titrated in the usual way, was used throughout. The sheep's blood was obtained from the jugular vein and collected into 1 per cent. sodium citrate solution made up in physiologic sodium chlorid solution. The cells were then washed in salt solution from five to seven times at 3,000 revolutions per minute, or until the supernatant solution was free from albumin by the heat and acetic acid test. A 2.5 per cent. suspension of washed sheep cells was made and used. They used a 0.85 per cent. salt solution. On each day of the test the reagents were titrated for their respective values. Sheep cells, 0.5 c.c. of a 2.5 per cent. suspension, were added to each tube and incubated in the water bath at 37 C. The smallest amount which produced complete hemolysis was read and noted. The tubes were placed in the water bath for one-half hour at 37 C., at the end of which time one unit of amboceptor and one unit of sheep cells are added. The rack was again incubated in the water bath for one-half hour and a reading made at the lowest point at which hemolysis was complete. This amount of complement was then taken for the unit and used in the test. Six tubes containing, respectively, from one to six units of amboceptor, minus complement, were used as a control for that reagent, and the complement control arranged in the same way, omitting the amboceptor. All serums were activated at 56 C. for one-half hour; 0.15 c.c. of serum was used throughout. From their study of this series, in which the complement fixation reaction was used as an aid in diagnosis and not as a control in treatment, the writers consider that sufficient information may be gained by the application of this test to warrant its routine application. If their observations were reasonably accurate, and 69 per cent. of active moderately advanced cases give a reaction compared with 16 per cent. reacting in cases not proved tuberculous, they feel that the test is of value and should be included in the routine examination, but should not be relied on without additional and confirmatory evidence. A frank reaction calls for a careful study of the case to ascertain the presence or absence of an active tuberculous lesion. They found no tendency to cross fixation with the Wassermann reaction. In some open advanced cases of pulmonary tuberculosis no reaction occurred, probably because the cells had lost their power of reaction owing to their prolonged saturation with specific toxins. A Wassermann test should be made in all cases of suspected tuberculosis, as the two diseases may be present at the same time. The test is of the greatest help in differential diagnosis; it also acts as a stimulus to more careful clinical observation.

5. The Late Complications of Gunshot Wounds of the Chest.—John B. McDougall, in order to study the later course of soldiers discharged after treatment for gunshot wounds of the chest ,sent out, at intervals, to the discharged man's next-of-kin, the form used by the Medical Research Committee, with the request that it be filled and returned. He was surprised to find that over ninety per cent. of the cases have been followed up at four to six monthly intervals. In some cases the symptoms complained of were grossly exaggerated, but on the whole, the answers were given concisely and well. Many of the cases were more fully investigated

by private correspondence. In this way he was able to compile a complete record of 139 cases from the time of injury, and to trace the clinical history of each case through field ambulance, casualty clearing station, base hospital in France, hospital and convalescent home in England, and, finally, to add notes on the subsequent history as it affected the original disability. The following summary is based upon the study of the correlation between the early clinical symptoms and signs and the late complications of chest wounds. Wounds of the chest wall, involving the muscles of the shoulder-girdle, give rise to much disability in the free movements of the arms. Fracture of the scapula is specially associated with impairment of function. If there is no intrapulmonary or intrapleural damage at the time of injury the men return to duty in the army in one to three months and are fit for service abroad. Collapse and contralateral collapse was found in 25 cases in the entire series. In 9 cases collapse occurred without perforation of the chest. Contralateral collapse, partial or total, was found in 10 cases. There is no evidence to prove that collapse, *per se*, is responsible for any of the after-effects of gunshot wounds of the chest, and in a study of the influenza cases infection is not found specially in cases which showed this phenomenon. The notes from the home hospitals show that in every case where the condition had been suspected in France no physical signs were present over the lung in question at the time of discharge from hospital in England. It is well known that even in the "acute" stages of collapse or contralateral collapse, localized or massive, there may be no symptoms beyond slight dyspnea and cough. Seventy-three cases come under the heading of hemothorax (sterile). If the effusion has been small three may be no physical signs in the chest three months after injury. When the effusion is large, however, there may be evidences on the objective side of limitation of movement of the lung on the same side, on the subjective side, of dyspnea on exertion and dull aching pain, probably due to fibrinous adhesions at the lower margin of the lung. Every case was able to return to duty in the army in two or three months, but 37 cases which had large effusions aspirated were only fit for light duty at home after an illness lasting three to five months. Five cases showed hemothorax (infected), 1 with encapsulated diplococci, 1 with a coliform organism, 2 with staphylococci, and 1 with Gram-positive streptococcus. In none of these was rib resection performed, the guiding principle being that the general condition, plus the physical signs, were of more value in coming to a decision in favor of operative interference than absolute reliance on the temperature chart and bacteriological examination. There were 17 cases of infected hemothorax in which rib resection was performed. In 4 of these a foreign body (visible to *x*-ray examination) was present in lung or pleura, and in 13 no foreign body was present. The disability in old cases of infected hemothorax is almost always the result of pleural adhesions. The breaking down of the adhesions in cases where a foreign body is retained in the lungs results in great relief. There were 26 cases in the writer's series who had evidences of a foreign body in the lung and yet who had no physical signs of infected hemothorax or septic pneumonia.

1. Preventive Treatment in Influenza. Sir Thomas Horder considers the subject under four headings: 1. The Prevention of Epidemics. 2. Prophylaxis as it concerns the community. 3. Prophylaxis as it concerns the individual. 4. The control of the epidemic when it arrives. The first heading is dismissed with brief consideration because of the barrenness of results of a practical kind concerning the factors which determine epidemics of disease, and especially the factors which determine epidemics of influenza. Under the second heading, after discussing briefly the generally accepted view regarding the maintenance of a high standard of general health in the country as a safeguard against an epidemic, Sir Thomas Horder expresses the belief that, even if we succeeded in converting a country of C 3 citizens into one the great majority of whose members would pass the medical boards as A1 individuals, we would not thereby protect ourselves against influenza and its ravages. Some micro-organisms are prone to attack and to efect persons of low general resistance: tubercle and the more chronic pyogenetic infections are examples of this. But in another group of micro-organisms infection depends much more upon the virulence of their elements than upon the resistance of the host; the influenza virus certainly belongs to this group. As a barrier against the first class of micro-organisms there is no doubt that to keep the general standard of health at a high level is the best form of prevention: to provide air, light, exercise, rest and good food. But for defence against infecting agents of the latter class we seem to need a much more specific means of prevention. In the matter of prophylaxis in regard to the individual, the sound advice to keep himself fit, on general grounds, unfortunately does not really touch the root of the matter, any more than keeping the whole community fit is likely to ward off an epidemic. This leads at once to the biggest gap of all in our knowledge of the disease: we are still without any certainty as to the essential causative agent in influenza. In the present state of our knowledge the available materials for preventive inoculation "against influenza" are not very convincing in regard to their specific value. When the epidemic has arrived the question resolves itself into prompt and thorough isolation of the patient, quarantine at ports, early diagnosis and notification, and a proper and adequate system of hospitalization. The last condition, hospitalization, is discussed in considerable detail. The great need is organized research and organized hospitalization.

September 4, 1919, xxvii, 49.

Evolution of Syphilography in France.—Jeanselme lectured on this subject to medical students from the United States last June. He traces the presence of the malady in France to the edict of 1497 when Parliament ordered the deportation of all strangers of both sexes who suffered from the "great pox" from the city of Paris. The first syphilographer to write up the disease in France was Bethencourt whose book is dated 1527. He recognized both venereal and accidental transmission as well as hereditary transmission. He described the local and general infections and knew of visceral syphilis. At a later period Thierry de Héry, who is said to have been present when the army of Francis I was attacked by the disease in Italy, mentioned the characteristic induration of the chancre as the essential fact of diagnosis. In 1579 appeared the work of Fernelius of Amiens on the best treatment of the disease. Bethencourt had advocated mercury while the former preferred guaiac. No other prominent writer is mentioned until we come to Astruc who despite his great learning had more crude ideas of the malady than his predecessors and like others of the XVIII century confounded syphilis with gonorrhea. This confusion persisted until the time of Ricord, who isolated gonorrhea from syphilis and established the dualism of the venereal ulcers but who himself fell into the error of pronouncing against the contagion of secondary syphilis. The mistake was rectified by his pupil Bassereau, whose interest in the disease seems to have afterwar dabated while another pupil, Fournier, placed the finishing tuoches on the work of the Ricord school of clinicians and experimenters. An outgrowth of a different sort of activity, to-wit, animal experiment, row came along in the classic labors of the heads of the Pasteur Institute. While the merit of discovering

the spirochete does not belong to France, Bordet and Gengou laid the foundation for the Wassermann reaction. The use of arsenic as antisyphilitic belongs originally to France, for Gautier used cacodylates before the introduction of arsenobenzole.

Etiology of Appendicitis.—Riff discriminates between the incidental involvement of the appendix in some general malady and the idiopathic and essential form which, however much it varies in expression, has a common pathogeny. He upholds the views enunciated long ago by Letulle and later corroborated and developed by Aschoff. These comprise the essentially cavitary origin, the autochthonous beginning—disposing of the doctrine of propagation from the cecum, and the origin in a minute cavitary abrasion of the mucosa. Given one or more slight defects in the cavitary epithelium, infection by pyogenic cocci is readily accomplished. Appendicitis never begins as catarrh of the organ as a whole. Simple as is this doctrine it is weak in one respect, for it is difficult to ascertain or imagine how the primitive abrasion arises unless from the activities of intestinal parasites and foreign bodies. Are the pyogenic cocci themselves able to cause these abrasions? This possibility would involve predisposing causes such as stasis in the organ. Aschoff accepts this view in his dictum "no stasis, no appendicitis." Stasis excites to virulence the microorganisms in the canal. Appendicitis as a result of serial crises is readily intelligible. for one attack by facilitating stasis and causing a deposit of mineral matter must pave the way for others. The sensible parasites, such as tenia, ascaris, and oxyuris, can readily supply the initial lesion. From this point on Riff takes up all the arguments in favor of the verminous theory and by reason of the great frequency of the oxyuris he makes it responsible for much of the disease as encountered today. Letulle and Aschoff were unable to find the oxyuris often, but this was not because of its absence. Systemic search will discover its presence. The author has worked in this direction for a number of years and has examined 152 appendixes subjected to every variety of inflammation and from patients of every age. Only 13 per cent. were quite without evidences of parasitism in the appendix, such as ova. Oxyuris, trichocephalus, and lumbricoids were all represented. The war interrupted his work, but since returning to the latter he has examined sixty-three more appendices and has found the oxyuris so omnipresent that he holds it responsible for most cases of appendicitis. He has evolved a complete "oxyuris theory" which explains the incidence of the disease in a very natural manner.

New Viewpoints on Obesity.—Gigon refers to the corpulence of the beer drinker as toxic in quality and not mere overnutrition. The like holds good for corpulence due to gluttony. It is extremely common and easy to treat. The type of sufferer is the plethoric, red-faced man who often presents alterations of the liver and pancreas or circulatory apparatus. He is likely to be hypertensive. The author believes that acute pancreatitis is almost limited to the corpulent. Perhaps akin to the toxic type is the corpulence which follows typhoid fever and pneumonia. This is not ascribed to compensation following emaciation and return of appetite, for the author sees it in syphilis and tuberculosis as part of the disease. As in the preceding there are apt to be changes in the liver and pancreas. A third group, the endocrinic, may be associated with several of the endocrine bodies as the gonads, thyroid and hypophysis. Of much interest are the nervous forms. Insanity at times begins by taking on weight and nervous influence alone can cause the putting on as well as loss of adipose. A fifth form is known as the atonic and is well known. To understand corpulence as a disease we must study pathological emaciation as well. The conditions which produce corpulence seem able to produce emaciation. Gluttony in a paretic treated by the author did not lead to corpulence, but to progressive emaciation. The author set the latter down to the influence of central nervous disease. The case is but one of many of the same type. In a case of emaciation in a beer drinker, study of the individual over some time led to the diagnosis of a pluriglandular syndrome. He not only drank much beer, but was gluttonous. He recovered his weight on a reduced diet and physical rest. It is evident that the fat man, like the thin man, is not always what he seems in that what seems physiological and natural is really pathological.

Gazette des Hôpitaux.

November 8, 1919, xcii, 68.

Proteinotherapy.—Cassan defines this subject as follows: It is a method of treatment in which one utilizes certain proteins in the management of diseases—chiefly infectious—and which is wider than the conception involved in proteose or peptone therapy in that it can include any substance which contains protein and is used in the treatment of disease. Thus whole blood treatment, as in transfusion, comes under the head of protein therapy. The subject goes back originally to Koch's tuberculin and includes the work of Wright on vaccinotherapy. For some reason unknown the author seems to ignore the use of antitoxins, perhaps because of the mode of action. Beginning with bacteriotherapy the next stage comprised the use of bacillary extracts which are technically albumoses and this precipitated the study of various proteins. Mixtures of bacteria with albumoses were used with great success in typhoid fever. Later albumoses were tested alone and one form was milk which having been boiled contained an albumose. Milk was injected and even transfused, but the danger of fat embolism led to its partial abandonment. Later Nolf devised his peptone injection treatment for typhoid, and other forms of protein therapy have continued to appear. At present the following have been used: Whole blood, plasma, serum; milk; substances classed as albumoses; substances classed as peptones; polypeptids. Blood, with or without preliminary treatment, is of course of value aside from its protein content as a reconstituent. The intravenous method is the choice in all proteintherapy. The infections thus far treated with good results are the typhoid group of fevers, typhus, influenza, tuberculosis, erysipelas, scarlatina, etc. Of noninfectious conditions hemorrhages are the principal ones to be treated in this manner. The most recent advances are along the lines of gonorrhea and polyarticular rheumatism. The former has long been treated with vaccines, but the author has of late obtained good results from the intramuscular injections of boiled milk with special reference to complications. Nothing is said of the use of vegetable proteins which are being as increasingly employed in America.

Is Influenza a Spirochetosis?—Blood studies of cases of the pandemic which occurred at Mentone, as well as sputum finds, having proved negative the urine was examined and a spirochete found in 8 out of 12 cases. Further tests appeared to show that this organism was quite constantly present. It differed from the known spirochetes, and was not pathogenic to guinea pigs. The article in question first appeared in 1918, and as nothing has come of the alleged discovery, it was presumably a false alarm.—*Revista Ospedaliera.*

Insanity Among the Jews.—It is stated by Becker that the Jew has a larger per cent. of insanity than other nations but less alcoholism and epilepsy. This excess is due simply to the fact that the Jew is a brain worker. That there is more congenital debility among Jews comes from the highly developed family sense. These children are carefully tended and live longer, so that the excess is not an absolute one. The excess of senile dementia also has a simple explanation. for the Jew lives longer than the Gentile and hence there must be more dementia due to advanced age. The excess in maniac-depressive insanity and dementia precox and in phobias, hysteria and neurasthenia is not so readily explained and inbreeding is rejected as a factor. It is here that we must invoke the fact already mentioned that the Jew is naturally a brain worker.

Book Reviews.

THE SOUL IN SUFFERING, a Practical Application of Spiritual Truths. By ROBERT S. CARROLL, M.D., Medical Director, Highland Hospital, Asheville, North Carolina, Author of "The Mastery of Nervousness." New York: The MacMillan Company, 1919.

THE book is well summarized in the Introductory Note: "It essays to bring a step closer the practical benefits....of medical science and the highest aspirations of our religion." It is conscientiously written, carefully thought out. Its style is its real drawback. This varies between the ponderous polysyllabic and the flowery. It was evidently written for the student, rather than for the patient.

THE MEDICAL TREATMENT OF CANCER. By L. DUNCAN BULKLEY, M.D., Senior Physician to the New York Skin and Cancer Hospital, etc. Philadelphia: F. A. Davis Company, 1919.

SOME day when it dawns upon pathologists and clinicians that, however much of a surgical disease cancer may be in its later stages, in its inception it is as purely medical as gout or diabetes, the names of Bell, Bulkley and a few other "cranks" will receive the honor that the profession of medicine gives, though sometimes tardily, to the discoverers of great truths. The author of this book is indefatigable in preaching this still unpopular doctrine, for this is the third book he has published on cancer as a medical disease. Dr. Bulkley's belief, shared in by an increasing number of medical practitioners, is that primarily cancer is due to a defect in metabolism and that, with the correction of this defect the disease may be arrested, although, of course, if the growth has attained such a size as to interfere with the functions of certain vital organs or is poisoning the system by its secretion, it must be removed by surgical means. Specific directions as to the dietetic and other non-surgical methods of treatment are given in this volume, which is full of interest and worthy of careful study by every practitioner, whether internest or surgeon, and whatever views he may entertain regarding the nature of cancer and its treatment. If he only reads it with the intention of refuting its arguments, he will have inevitably broadened his views thereby and will have learned something of cancer that he did not know before.

QUARTERLY MEDICAL CLINICS. A Series of Consecutive Clinical Demonstrations and Lectures. By FRANK SMITHIES, M.D., F.A.C.P. Augustana Hospital, Chicago. Volume 1. Number 2. January-April, 1919. St. Louis: Medicine and Surgery Publishing Company, Inc.

THE second number of this quarterly presents cases XVI to XXVIII inclusive in a volume of about 220 pages. Four "stomach cases" give an opportunity for a rather extensive discussion of the diagnosis, symptomatology, and treatment of gastric conditions, especially peptic ulcer and gumma. This opportunity is seized with such energy and the discussion is so ample and illuminating that a reader is sure to learn much from its perusal. The other cases are of equal interest and are discussed with a similar enthusiasm. This number is equal in every respect to the first and strengthens the opinion that this quarterly is to become a valuable item in medical literature.

A TEXT-BOOK OF PHYSIOLOGY. By MARTIN FLACK, C. B.E., M.B., B.Ch. (Oxon.), Research Staff, Department of Applied Physiology, Medical Research Committee, and LEONARD HILL, M.B., F.R.S., Director of Applied Physiology Department Medical Research Committee. Illustrated. New York: Longmans, Green & Co., 1919.

THE preparation of this text-book was begun before the war and not a little of the text prepared at that time required revision before the book was finished. Much of the advance which physiology has made during these past five years has therefore been incorporated. The authors "have avoided burdening the students memory with the names of authorities," a practice, the reviewer feels, that is not wholly undeserving of criticism. The presence of references at the bottom of a page is not necessarily a burden to the memory and often proves a great convenience when investigating some particular point. Besides, the presence of the reference may prove the stimulus to an investigation of the literature more pleasantly applied than the tiresome hunt through an Index. The book was written "primarily to meet the requirements of the medical student" but as a complete and modern physiology is ever a valuable aid to the practitioner both in diagnosis and treatment should "also prove of value to the general practitioner." The style is uniform throughout and the illustrations are profuse and often excellent. The work is altogether such a one as might be expected from its eminent authors.

PSYCHIATRIC-NEUROLOGIC EXAMINATION METHODS With Special Reference to the Significance of Signs and Symptoms. By DR. AUGUST WIMMER, Director St. Hans Hospital, Roskilde, near Copenhagen, Denmark. Authorized translation by ANDREA W. HOISHOLT, M.D., Medical Superintendent Napa State Hospital; Professor of Psychiatry, Medical Department Leland Stanford Junior University, San Francisco, California. St. Louis: C. V. Mosby Company, 1919.

THIS is a compendium of abbreviated outlines giving references to fundamental features in symptomatology and intended as a practical guide in making psychiatric-neurologic examinations; it also includes part of the general symptomatology belonging to psycho-neuropathology, with, in several places, short introductory presentations of the normal psychological or anatomo-physiological data. The work does not claim to be a complete treatise on diagnostics since, to make a clear diagnosis here as elsewhere in medicine, it is necessary to be acquainted with the special pathology and to be in possession of clinical experience, but it does provide for a methodical examination which is in itself a long step toward this goal. The three chapters deal with the Anamnesis, by schedule and symptoms; the Pyschic State, by a full examination schedule; and the Somatic State, by the examination scheme. There is a complete index, and apparently nothing is lost in the translation.

IDO Exhaustive Text-Book of the International Language of the Delegation and Fundamentals of an Artificial International Language. By Dr. MAX TALMEY. Author of "Practical and Theoretical Esperanto," "Defects of Esperanto," etc. New York: Ido Press, 1919.

IDO is the name of the new international language devised by the Marquis L. de Beaufort or Beaufront (it is written both ways in the author's preface) to supplant Esperanto, the good features of which it aims to preserve while avoiding its many great defects. It certainly, to the Ido-ignorant observer, has avoided the defect of ugliness which Esperanto presents to the eye, with its many js and ks and diacritical marks. This is the first book in English for instruction in Ido; it was ready for publication in the summer of 1914, but the World War has delayed its appearance until now. Those interested in these attempts to supply the world with a universal speech can do no better than study this manual, for of all the artificial languages thus far fabricated Ido appears to be the simplest and most practical.

OUR NERVOUS FRIENDS. Illustrating the Mastery of Nervousness. By ROBERT S. CARROLL, M.D., Medical Director Highland Hospital, Asheville, North Carolina: Author of "The Mastery of Nervousness," "The Soul in Suffering." New York: The Macmillan Company, 1919.

THE author of this book endeavors to depict in the form of short stories the causes of many cases of nervousness and worse, and to indicate in many of them the means whereby the sufferer may be restored to the normal. The protean forms of "nervousness" afford many subjects for interesting stories which de Maupassant or Poe could have made most thrilling. It is no disparagement to the author to say that he does not measure up to the genius of either of those mentioned as a story writer, but nevertheless he has made a most readable book which can do no harm to any, even the youngest person, and which might perchance give to the older ones, to those who may be already starting in the downward path of "nerves," a hint or a shock that will open their eyes to their danger and save them even on the brink of the precipice.

Society Reports.

THE AMERICAN PEDIATRIC SOCIETY.

Thirty-first Annual Meeting, Held in Atlantic City, N. J., June 16, 17, and 18, 1919.

THE PRESIDENT, DR. EDWIN E. GRAHAM, IN THE CHAIR.

President's Address: Foreign Bodies in the Air and Food Passages.—Dr. EDWIN E. GRAHAM of Philadelphia delivered this address, which he said was based on observations made on a comparatively large number of cases of foreign body in the air passages and a smaller number of cases of foreign body in the food passages. For the opportunity of seeing some of these cases he said he was indebted to Dr. Chevalier Jackson. Histories and bronchoscopic charts of a number of the most interesting cases were presented. In summarizing he said that it was reasonable to believe that foreign bodies in the air and food passages in children were much more common than was supposed. Statistics indicated that about 66 per cent. of the cases of foreign body in the air passages occurred in children. The fact that there was a period of latency of symptoms which followed the violent dyspnea and choking attack, and later the gradual onset and chronic character of the symptoms might lead one to fail to suspect the presence of a foreign body. A study of the histories of many of the cases showed that certainly foreign bodies were frequently overlooked. The symptoms varied greatly. The peanut kernel set up immediately a severe laryngitis, tracheitis, and bronchitis. In the peanut cases an older child might survive the acute symptoms, but would almost surely develop pneumonia. Metal objects remained in the lungs for a very long while and did comparatively little damage. There were some foreign bodies that did not cast a shadow on the *x*-ray plate. In such instances the presence of a foreign body might be diagnosed by allowing the patient to swallow a bismuth-filled capsule. The *x*-ray would then show the location of the bismuth capsule held in position in the esophagus by the foreign body. The patient should not be urged to cough with the hope of expelling a foreign body inhaled into the lungs, as foreign bodies were very rarely coughed up. The physical signs and symptoms varied according to the composition, form, shape, and size of the foreign body. One should suspect a foreign body if the following conditions were present: An unexplained leucocytosis, localized symptoms in one lung that did not clear up under treatment; no tubercle bacilli in the sputum, and a gradual failure in weight and strength. There were no contraindications to bronchoscopy except perhaps weakness in the patient, and when this occurred time should be given the individual to rally in part. Children did not require the administration of an anesthetic for performing bronchoscopy. The necessity of taking a radiograph of every case that gave a history of swallowing a foreign body could not be too strongly emphasized. The asthmatoid wheeze was a symptom of considerable importance as indicating the presence of a foreign body in the lung.

A Study of the Lactose, Fat, and Protein Content of Woman's Milk—Dr. FRITZ B. TALBOT of Boston presented this communication, giving the results of an investigation on the composition of milk at different stages of lactation. The estimations were made by the newer methods, which made it possible to quantitate accurately the fat, protein, and carbohydrate from small samples of milk. It was found that the average quantity of lactose in sixty samples of breast milk was 7.19 per cent. There was a general tendency for the strength of the lactose to increase throughout the period of lactation. The percentage of fats in the milk of different women varied within wide limits. The average amount of fat in the mixed samples was 3 per cent. The average amount of fat in thirty-five samples taken only from wet nurses was 4.18 per cent. It seemed more probable that the percentage of fat depended more upon how completely the breasts were drained and the amount of the late milk which got into the samples than upon the stage of lactation. As lactation progressed there was a general tendency for the amount of protein to diminish. The difference in the percentage of lactose from the beginning to the end of nursing rarely exceeded 1 per cent. There was a greater variation in the percentage of fat, but as a rule this was less than 4 per cent. The percentage of protein varied very little and was sometimes lower after nursing and sometimes higher. In studying the variations in the composition of milk taken at three-hour periods in the course of a single day, the volume of milk was shown to have a tendency to diminish as the day went on. After midnight the percentage of fat was found to be higher as a rule. The variation in the amount of lactose and protein, however, was very slight.

Dr. L. EMMETT HOLT of New York stated that Dr. Talbot's figures for sugar were about what they had found in their laboratory. Many disturbances of digestion were attributed to fat which in reality were due to sugar. A baby might be gaining in weight and yet have eight or ten thin, sour, green stools per day, and it could be shown that this diarrhea was due to the volatile fatty acids caused by the sugar. Clinically the way to handle these cases was to dilute the milk and change the frequency of feeding. An examination of the stools in these cases would reveal the presence of fat, and this led to the assumption that it was the fat in the diet that was causing the disturbance. The reason the stools contained fat was because the fermentation of the sugar caused diarrhea and interfered with fat digestion and absorption. If the child did not vomit the disturbance might be attributed to the sugar.

Dr. DEWITT H. SHERMAN of Buffalo said he understood Dr. Talbot to say the protein in the milk bore no relation to the high carbohydrate content. If that was so, would it not be possible to overcome these conditions caused by a large amount of sugar by the addition of some powdered protein preparation, thus changing the ratio of the food elements?

Dr. TALBOT said he wished to emphasize that these were normal figures. The children who, in later lactation were getting eight per cent. of sugar, were without watery stools, so they concluded that this was a normal ration for this period of lactation. In regard to the question as to whether sugar fermentation would be diminished by changing the relative proportions of the food elements by overbalancing the high carbohydrates with more protein, he thought the thing to do was to reduce the sugar.

The Pathogenesis of Certain Nutritional Disorders.—Dr. W. MCKIM MARRIOTT of St. Louis presented this paper. He said the first condition considered was the severe and acute toxic state observed in infants who had suffered from a severe watery diarrhea. The condition had been referred to as an "alimentary intoxication" because the administration of food resulted in an increase of all the symptoms. A more rational view was that the giving of food, especially easily fermentable carbohydrate, led to increased water loss from the body by way of the bowel, and that the symptoms may be entirely referred to water loss. The blood plasma of infants suffering from this condition was invariably greatly concentrated. The protein of the serum of normal infants averaged 6 per cent.; in those desiccated, as the result of diarrhea, the protein might rise as high as 9 or 10 per cent. This desiccation of the body explained the great loss of weight observed in these children. The decrease in blood volume brought about by desiccation led to a greatly diminished volume flow of the blood. This had been measured by the calorimetric method of Stewart and had been found to be decreased to as low as 15 per cent. of the normal. It had been demonstrated experimentally in animals by Gesell and by Almroth Wright that a decreased volume flow of the blood resulted in a decreased alkaline reserve of the blood, or, in other words, acidosis. The acidosis was evidently the result of suboxidation in the tissues. An additional factor was retention of acids in the body through failure of excretion by the kidneys. Renal activity was greatly decreased due to the concentration of the blood and the poor volume flow of the blood. The acidosis was the cause of the "air hunger" type of respiration observed in some of these infants. When blood volume was diminished arteriolar constriction occurred, and this might be considered as a compensatory mechanism to maintain blood pressure. Constriction of the arterioles resulted in a piling up of red

corpuscles in the capillaries, and this explains the peculiar gray color of these infants. The corpuscular counts on the capillary blood were distinctly higher than in venous blood. Dehydration of the blood resulted in a disturbance of the heat regulatory mechanism and fever occurred. The temperature fell when normal conditions in the blood were restored. In experimental anhydremia in animals and in the infants under consideration vomiting was a frequent symptom. It ceased in most instances when sufficient fluid was introduced into the body. The diminished volume flow of the blood rendered conditions in the intestinal tract unfavorable for digestion and absorption of food. The whole clinical picture presented by these infants resembled closely that seen in "wound shock." In both conditions there was a diminished blood volume and volume flow, and the resulting arteriolar constriction, low blood pressure, and frequently acidosis. The cause for the diminished blood volume was quite different, however, in shock and in the infants, but the end result was practically the same. The term "anhydremia" or "anhydremic intoxication" was accurately descriptive of the condition here considered and was preferable to the undesirable term of Finkelstein, "Alimentär-Intoxikation." Anhydremia occurred from other causes than diarrhea. Diminished fluid intake or vomiting from any cause might lead to the condition. Fever and high external temperatures greatly increased the loss of fluid from the body and, unless this loss was made up, anhydremia would result. The symptomatology of anhydremia was the same, no matter what the original etiological factor. The treatment was also the same. In treating the condition fluid in large amounts must be administered. The usual methods were often ineffective, and intraperitoneal injection of normal saline must be resorted to. The injections must be repeated at frequent intervals. A small infant might receive as much as 1500 c.c. of fluid in this way in the course of 24 hours, before the blood was restored to its normal concentration. In some instances it was impossible to restore normal conditions; when this was the case the infants invariably died. When it was possible to introduce sufficient fluid and have it absorbed and retained, a rapid cessation of all the symptoms occurred in the majority of instances. The intravenous injection of 10 per cent. glucose solutions at frequent intervals was often a valuable adjunct to the saline injections. The second nutritional disturbance to be considered was also often the result of a severe diarrhea, although it might result from any cause which led to the ingestion and absorption of less food than was necessary to maintain activity and growth. The condition referred to was the one known as "Marasmus," "Atrophy," or "Dekomposition." The condition was analagous to anhydremia; it was the result of insufficient food, whereas anhydremia was the resudt of insufficient water. The term "Athrepsia" was accurately descriptive.

In athrepsia the protein of the blood plasma was somewhat diminished, and it had been shown by Bayliss that when the colloids of the blood were diminished it lost its power to retain water. A diminution of blood protein as the result of partial starvation led to a decreased blood volume. The blood atrophied as well as the rest of the body. The volume flow of the blood was decreased in this condition although rarely as greatly as in anhydremia. There was the same constriction of the arterioles, the same color of the skin. Such infants, with a volume flow of the blood already greatly diminished, could not withstand even a moderate loss of water without succumbing to the more serious manifestations of decreased volume flow. This explained the fact that it was the poorly nourished infants who most readily fell into the severe toxic states. The obvious treatment of athreptic infants was the administration of considerable amounts of food. Unfortunately the tolerance to food was low, probably on account of the poor circulation of the atrophied blood in the mesenteric vessels. If food could be taken the blood was gradually restored to normal but the process might be a long one. The period of repair might be somewhat shortened by artificially increasing the colloids of the blood. This might be done by a transfusion or almost equally well by frequently repeated injections of gum acacia, a harmless colloid. The best results in feeding with artificial food had been obtained with whole lactic acid milk to which a mixture of carbohydrates was added. The most suitable carbohydrates were dextrin and glucose; maltose was also serviceable. Commercial "Corn Syrup" was such a mixture as had proven most effective in his hands. It was often necessary to feed over 200 calories per kilo of body weight. Unless sufficient food was given all other means of cure were useless. The acacia injections were an adjunct, not a substitute for food.

Dr. Oscar M. Schloss of New York said that, while pediatric literature contained many references to the digestibility of fat, protein, and carbohydrate, very little was said about water. It seemed that a proper proportion of water was a most important factor, as Dr. Marriott's paper had illustrated. Those children who were suffering from intoxication were always recognized as being in a state of dehydration. He had a number of times seen acidosis disappear without the administration of sodium bicarbonate, the explanation being as Dr. Marriott had shown.

Dr. Isaac Abt of Chicago spoke of the possible impression Dr. Marriott's paper might have on the pediatrist. He said that many attempts had been made to classify intestinal disorders, both by clinicians and bacteriologists, and they all knew how futile such attempts had been. The most valuable classification they had was based on food disturbance. It seemed that by noting the effects of certain foods in various conditions of health and disease the most important basis for the classification of nutritional disturbances would be furnished. Dr. Marriott had not referred to this side of the question and, while he had made an important addition to the chemistry and pathology, the important question was how to prevent pathology.

Dr. Marriott, in closing, said that in the paper no attempt had been made to discuss the etiology of diarrhea. He felt that the prophylaxis of these conditions which he had discussed was the prophylaxis of diarrhea, which he considered as a local condition in the intestinal tract and merely the end result produced by any cause whatever.

A Study of the Relationship of Convulsions in Infancy and Childhood to Epilepsy.—Dr. John Lovett Morse of Boston presented a study of 107 cases in which the primary cause for attendance was convulsions. No cases were included in which there were any evidences of acute or chronic cerebral disease. The objects in the study were, first, to determine what proportion of the children, otherwise apparently normal, having convulsions had epilepsy or developed it later; second, to find out, if possible, whether there was anything in the history or in the manner of the development of the convulsions to show whether or not they were manifestations of epilepsy, or whether they would be followed by or develop into epilepsy later. Ten of the cases showed evidences of spasmophilia. The convulsions ceased in all cases, but one of the babies became feeble-minded. It was possible that in this instance the convulsions were due to some other cause than the spasmophilia. It would seem, therefore, that convulsions which occurred in babies with spasmophilia and which were presumably a manifestation of spasmophilia were not likely to lead to the development of epilepsy later. In three instances the convulsions occurred in the course of whooping-cough. Epilepsy developed in one of these children. Convulsions occurring in the course of whooping-cough must, therefore, be regarded seriously. There were 39 cases in which there was a single convulsion or a series of convulsions at the onset of some acute disease or with an attack of acute indigestion. Thirty-five of these children recovered; two became epileptic and feeble-minded, and a third had petit mal; a fourth might or might not be epileptic. There were 55 cases in which there had been repeated convulsions during a considerable period or in which there had been repeated attacks suggesting petit mal. Taking seven years as an arbitrary standard, only 21 of these cases could be considered normal at present. An attempt had been made to determine if there was anything in the history or character of the convulsions which would aid in determining in a given case whether epilepsy was likely to result in the future or not. The results of this attempt, however, had been rather unsatisfactory. It was impossible to tell from the nature

of the early attacks as to the nature of the attacks when epilepsy developed later. The longer the attacks had persisted the more probable was the diagnosis of epilepsy. When there was no apparent etiology or when the cause of the attacks was apparently an injury or severe labor, epilepsy was far more likely to develop than when the apparent cause was a disturbance in the digestive tract. The longer the attacks had persisted the more probable was the diagnosis of epilepsy. General impressions which could not be explained had a certain value in diagnosis. There was no way to determine immediately when a baby or child had a convulsion, or had repeated convulsions, or repeated attacks suggesting petit mal, whether or not it had epilepsy or would develop it later.

Dr. HENRY KOPLIK of New York said that in the main he agreed with Dr. Morse. In the vast majority of spasmophiliacs epilepsy as that term was understood did not occur later in life. If a child was otherwise normal one should be cautious in making a diagnosis of epilepsy. It was well to remember that spasmophilia might occur later in life. He had recently seen a child who had convulsions for the first time at the age of five years. Another point was that one should be careful about making a diagnosis of epilepsy during the early years of childhood if there was no history of epilepsy in the family.

Dr. L. R. DE BUYS of New Orleans asked Dr. Morse if he classed children who had spells of "holding the breath" as spasmophiliacs, and whether or not he had met children of that type who had epilepsy later.

Dr. J. P. CROZER GRIFFITH of Philadelphia agreed that it was practically impossible to make a diagnosis of epilepsy early in life. In the newborn convulsions might be due to lesions caused at the time of birth and these might result in epilepsy. Pertussis might be the cause of convulsions but these children did not as a rule develop epilepsy. Convulsions due to indigestion did not as a rule result in epilepsy.

Dr. HENRY HEIMAN of New York said he had seen children develop coma and convulsions a few days after birth, and in such cases these symptoms might be due to venous apoplexy due to injury at the time of birth. The venous apoplexy was the result of blood oozing from the cortical area. The consequences in such a case depended upon how much of the blood clot would be absorbed and how much would organize. Possibly the early treatment of spasmophilia might prevent epilepsy.

Dr. L. EMMETT HOLT of New York said that it had been his experience that a large number of children who were expected to have epilepsy did not have it. The general practitioner and the neurologist were more apt to regard these children as prone to have epilepsy than was the pediatrist, because the pediatrist saw convulsions so often and the great majority of the children having them did not develop epilepsy. Recurring convulsions with a sharp rise of temperature, even if there was not indigestion present, were not serious in relation to epilepsy, but when a baby developed convulsions without rise of temperature and without assignable cause, they should be regarded with suspicion. Dr. Morse's assumption that convulsions during whooping-cough might lead to epilepsy later were based on insufficient data. Unless there was some underlying peculiarity of the nervous system epilepsy was not likely to follow the convulsions of whooping-cough. In reference to prognosis, the pediatrist should be taught the importance of prognosis. The tendency at present was to lay undue emphasis on diagnosis, and the student was likely to think that when he had made a diagnosis he had done all that was necessary.

Dr. ROWLAND G. FREEMAN of New York called attention to a point that had been considered of value by some, namely, that children under two years of age who had marked evidence of rickets were less likely to develop epilepsy.

Dr. SAMUEL S. ADAMS of Washington, D. C., agreed in the main with Dr. Morse. He said the most important point was to avoid casting the stigma of epilepsy on a child. Many of these cases of convulsions had some of the appearances of epilepsy, but he always made it a point to teach his students to be very careful about calling it epilepsy. In some children the onset of the infectious diseases was usually ushered in by convulsions but after the period of infectious diseases was passed the children no longer had convulsions.

Dr. HENRY L. K. SHAW of Albany said there was a tendency for the laity to take the position "Once an epileptic, always an epileptic." He had had several cases of undoubted epilepsy that to all intents and purposes recovered.

Dr. HENRY F. HELMHOLZ suggested that possibly acute conditions, particularly gastrointestinal disturbances, might be a factor in changing a latent into an active spasmophilia. The main point seemed to be that if there was temperature at the onset of illness, convulsions associated with it were not of great importance so far as the diagnosis of epilepsy was concerned.

Dr. FRITZ B. TALBOT emphasized the fact that in considering this whole question they were dealing with a symptom and not with a disease. If this symptom was due to spasmophilia they might expect to find some change in the blood calcium. They had determined the blood calcium in a small number of spasmophiliacs and found it lowered.

Dr. MORSE, in closing, stated that he had never considered breath holding as a symptom of spasmophilia. As to the birth hemorrhages, he had left those out as he had included no cases in which there was a sign of injury to the brain. He did not think that when a child had a convulsion, say only one a year, that it could be due to spasmophilia, for spasmophilia was present all the time and it did not seem that such being the case it would show itself so rarely.

Certain Aspects of Cutaneous Hypersensitiveness.—Dr. E. C. FLEISCHNER of San Francisco made this presentation. He cited experimental proof that cutaneous hypersensitiveness was not present in sensitized uninfected guinea pigs. He discussed the value of cutaneous hypersensitiveness in the diagnosis of chronic diseases of guinea pigs, including tuberculosis, abortion disease, rodent paratyphoid, and undulant Malta fever. The conclusion was reached that cutaneous hypersensitiveness was always an indication of the presence of a focus of infection. There was no evidence of its being an indication of immunity. He also demonstrated the similarity of *B. Militensis* infections in guinea pigs with those of the *Bacillus abortus*, giving conclusive evidence based on pathogenicity, apparently identical microscopical findings, gross changes in the viscera, cutaneous hypersensitiveness, and a certain amount of evidence of a positive serological relationship.

Quarantine and Disinfection in Scarlet Fever.—Dr. J. CLAXTON GITTINGS of Philadelphia, Lt. Col. M. C., U. S. A., read this paper, in which he stated that the first assignment of patients to the U. S. Army General Hospital No. 9 consisted of 139 cases of scarlet fever, transferred in February, 1918, to relieve the pressure in nearby camps. The hospital functionated in a hotel of the regular double "L" design, so well suited for quarantining two entire sections, isolating completely the sick from the healthy. The patients were admitted to the hospital in every stage of the fever, from the second to the thirty-fifth day, 20 per cent. being within the first five days of the disease. There was much chance for contagion from contact, and five cases developed in this way, two among attendants. A case was cited in which contagion resulted, presumably, from being dressed in the same dressing room with and after a patient who had a post-scarlet fever submaxillary adenitis. A minimum length of 42 days' quarantine was enforced. On the 40th day each patient was carefully examined by the assistant chief of medical service. Those who showed any abnormality in the throat, nose or ears were inspected by the throat and nose specialist, who decided whether the patients were potential carriers of contagion or not. At the end of the quarantine period 59 per cent. of the patients were ready for discharge; 41 per cent. required more or less treatment. The average period of quarantine was, therefore, 47 days, but this extension was due partly to several cases of mumps. At the end of quarantine each patient was given an orthodox bath, shampoo, change of clothing, and was then sent to a clean ward in another part of the building. All soiled

linen was soaked for two hours or more in 2 per cent. liquor cresolis solution before going to the laundry. Shoes, hats, and leather belts were exposed to formaldehyde gas in sealed closets a day. Blankets and woolen clothing were sterilized in the autoclave. After the evacuation of the ward, carpets and paper wadding were spread out in the air for two days, and were then brushed and stored. The floors, halls, beds, furniture, woodwork, and all flat surfaces were wiped and mopped with much of the 2 per cent. solution of cresolis. The mattresses and pillows were left on the beds and all windows were opened for three days. Within two weeks these wards were again occupied. Until February, 1919, there had not been another case of scarlet fever in this hospital. So far as could be learned none of these patients carried the contagion to any one in Lakewood or elsewhere. Of the 144 patients, 56 showed no defects of any kind; 10 showed defects which were ample cause for rejection from military duty, among these being gastric ulcer, valvular heart disease, hysteria, chorea, tuberculosis, and Graves' disease; 11 showed serious complications; 37 showed mild complications; and 13 suffered from cardiac disorders. Until the infecting organism of scarlet fever was demonstrated the proper length of quarantine was always open to argument. In accounting for the spread of this disease, the chronic carrier would seem to be the most likely agent, as in meningitis and diphtheria. *A priori* the unhealthy nasopharynx and throat might be under suspicion. Examination by throat specialists might enable us to retain the potential carrier and hasten the discharge of a healthy person. In mild cases 35 days at most might cover the danger period. The factor of the human carrier in contagion was being accepted to such an extent as to make it questionable whether anything but thorough cleansing was necessary. Formaldehyde gas with sufficient moisture would probably destroy the organism of scarlet fever, but that this optimum result was obtained was very doubtful. Disinfection and removal of dust from linens and woolens, floors and furniture, followed by thorough sunning and airing, appeared to be the real requirements for safety.

Dr. D. J. MILTON MILLER of Atlantic City asked what was to be their belief in reference to quarantine if they thought that desquamation from the epidermis was not contagious. If desquamation continued indefinitely, of course they could not continue to keep a patient under quarantine. The catarrhal symptoms, on the other hand, could not serve as a guide to the period of quarantine. He felt that until they had more definite information as to the period during which scarlet fever could be transmitted quarantine should be continued until desquamation was complete.

Dr. J. P. CROZER GRIFFITH of Philadelphia recalled that people used to believe that scarlet fever could be carried in clothing for many years. They now believed that scarlet fever was transmitted by personal contact. He did not think that desquamation was a reliable criterion as to the period of time during which scarlet fever was contagious. It was well to bear in mind that there were other skin diseases besides scarlet fever in which desquamation occurred and such a disease might be coexistent with scarlet fever.

Dr. HENRY HEIMAN of New York said they were to be congratulated in getting away from the time-honored superstition that scarlet fever was carried in clothing. A person in order to acquire the disease must come into contact with another person who had the disease or with a carrier. The disease was conveyed more easily by a person actually having the disease than by a healthy carrier. The susceptibility of children to measles was 90 to 95 per cent., while the susceptibility to scarlet fever was only 30 to 35 per cent.

Dr. J. MASON KNOX of Baltimore said he would like to know if anyone had data as to how long scarlet fever patients continued to have sore throats. The sore throat appeared before the eruption, and he had seen epidemics started by early cases before the eruption appeared. If there was any suspicion of the presence of scarlet fever it was more important that the patient should be isolated early in the course of the disease than later.

Dr. GITTINGS, in closing, said that he thought thirty days' quarantine was probably sufficient, but in the camps a period of six weeks was required. If there was any possibility that a child or susceptible person would come into contact with the convalescent patient it was better to continue the quarantine for six weeks.

A Study of the Cholesterol Metabolism of Infants.—Dr. K. D. BLACKFAN and Dr. J. L. GAMBLE of Baltimore presented this contribution, in which they stated that cholesterol, an important constituent of tissue cells, might also bear important relations to certain physiological processes. Cholesterol or substances very nearly identical were present in all natural foods. The difficulty of finding a food free from cholesterol or cholesterol substances had prevented satisfactory proof by animal feeding experiments as to whether or not cholesterol synthetized within the body. If cholesterol was not synthetized, an adequate amount must be provided in the food in order to maintain the chemical structure of the tissue cells and provide for growth. In the food of an infant the amount of cholesterol was roughly proportional to the amount of fat present. It had not been possible to detect any coptosterol in the stools of infants. Apparently none of the cholesterol excreted by an infant underwent reduction in the intestinal tract. This fact made it possible to study the "cholesterol balance" in infants. They had used the assumption that the finding of a consistently negative cholesterol balance in normal or gaining infants would indicate cholesterol synthesis. It had been necessary to modify considerably an existing colorometric method for measuring cholesterol in order to determine with accuracy the cholesterol content of milk and stools. The cholesterol balance of several infants had been determined. With one exception a large negative balance was found. It was proposed to obtain further data on this point. The results so far obtained suggested that cholesterol was synthetized within the body. The relation of cholesterol to maintenance and growth apparently did not depend on the amount of cholesterol in the food.

Certain Nutritional Disorders in Infants Associated with Proteolytic Intestinal Flora.—Dr. LANGLEY PORTER of San Francisco made this presentation. After reviewing the results of the investigations of Eserich, Moro, and others, who had established the knowledge of the stool flora of infants, he referred to the recent work of Kendall, Herter, and Torry, more particularly the recent demonstrations of the latter that it was possible to change the intestinal flora of dogs by feeding large quantities of dextrin or lactose. The charts presented, drawn up after the investigation of many stools evacuated by healthy children, showed that there was a standard flora in the intestines of healthy babies and children. Other charts based on the study of stools of children who suffered from different types of nutritional disturbances demonstrated that in such cases the flora in the intestines had departed from the normal. The normal stool showed a flora composed almost equally of aciduric and protein-splitting organisms. Normally, an antagonistic balance was maintained between these. In the groups of nutritional disorders studied, the flora all showed a predominance of proteolytic types of bacteria. These children all exhibited clinical disturbances evidenced by symptoms of toxemia. They all responded to the limitation of milk, meat, and egg-white, together with a diet high in lactose and dextrins, by a swing of the intestinal flora to a predominance of fermentative forms. With this change there occurred coincidentally an amelioration of the clinical symptoms. On a rational diet well being had been maintained and the stools had remained at a floral balance approximating the normal standard. The types of alimentary disturbance studied were the following: A type corresponding to the balance disturbance of Finkelstein, a similar unbalance in older children, acute alimentary intoxications, and subacute and chronic conditions of alimentary disturbance with symptoms of intoxication. In all of these the proteolytic organisms dominated the fecal flora. In all the patients the return to health was coincident with the establishment of a normal flora in the intestines. While they made no claim to having established an etiological relationship between these alimentary intoxications and the flora of the intestines, they held that the possibility of such a relationship could not be ignored and should be made the subject of further and more intensive investigations.

Dr. Henry Koplik of New York reviewed the principles of the Czerny and Finkelstein schools and stated that unless protein milk was properly made it rather hurt the baby and might cause a bloody diarrhea. Finkelstein had insisted upon this point and had installed his own plant for preparing albumin milk. Again, the milk must not be stored too long before it was prepared, but here they were in the hands of the purveyors of milk. Dr. Porter gave lemonade in these conditions while he eliminated all sour food and also sugar from the diet. Dr. Porter had obtained good results by his method and he (Dr. Koplik) had obtained good results with his method.

Dr. E. C. Fleischner of San Francisco thought it was much better to have a method based on a logical foundation than to proceed in an empirical way, and he felt that Dr. Porter had given them such a logical basis for the treatment of this type of infants. Where butyric acid fermentation was concerned it was better to leave the fat out of the diet, and he thought that was the method Dr. Porter had followed. If the etiological factor was the proteolytic anaerobes, as it frequently was, then to get at the root of the evil the protein element must be considered, and both fats and proteins must be eliminated, at least temporarily.

Dr. Porter, in closing, said that during the discussion allusion had been made to the Czerny school. The Czerny school had been of great value as a guide in the study of alimentary disturbances, but it was not like the law and the prophets, beyond criticism. He thought they had all recognized the fact that they could not feed high fats when the protein was low. This was shown by soapy stools when this kind of a diet was employed. He had been asked to discuss the butyric fermentation of the anaerobes. They were now at work on this subject and were very much at sea as to the rôle of the anaerobes. He believed it would be shown that the blood non-protein nitrogen would be increased when the anaerobes were high.

Transfusion in Infants and Children: The Indications and Dangers.—Dr. Henry Koplik of New York presented this communication to the effect that the application of transfusion in the new-born was as follows: (a) In cases of uncontrollable hemorrhage from wounds, umbilicus, or scalp hematoma. (b) In forms of frank melanemia with hemorrhage from the intestines, the subcutaneous and gastric hemorrhages. (c) Concealed melanemia in which the outward objective signs of hemorrhage were slight, such as occasional ecchymosis on the surface, but in which the evidence of internal hemorrhage was great, for instance, the critical loss of weight, intense anemia, amounting to the phenomena of exsanguination, very slight signs of hemorrhage from the intestine, with marked hemorrhage into cavities such as the subarachnoid space. (d) In cases of severe and continued hemorrhage among the new-born from surgical wounds, as circumcision, hemorrhages which were of parenchymatous character, and were exsanguinating to a degree. In these the conclusion, as in the hemorrhage beneath the scalp, was that there was a congenital condition present, a hemophilia. The best success in hemorrhages of the new-born was attained by prompt transfusion in a positive manner by the direct introduction of blood or citrated blood into the circulation. They had two methods from which to choose, and the time was scarcely ripe for a decision in favor of either. The direct introduction of full blood from donor to patient was the first method, and was called the Unger or syringe method (Lindemann); the second was the so-called citrated blood method (Lewisohn). The advantage of the first method was evident if in every case one could test the donor and recipient for hemolysis. The advantages of the second method were, first, that the blood could be transported at some distance, and that in an emergency the tests for hemolysis were unnecessary. He had used both methods and had found them both applicable. He felt that failures in many cases were due to the lack of delicate skill in the technique of the surgeon, and that a decision as to which method was best could be made only by an operator who had handled both methods. He had never seen a failure due to full normal blood or citrated blood; the technique had always been his criticism. He had seen cases in which the subcutaneous introduction of serum or even whole blood had absolutely failed to control hemorrhage. A single definite transfusion succeeded in combating symptoms in these cases, if they lived. Improvement in the patient's condition took place even where symptoms of sclerema, often looked upon as the beginning of a fatal issue, set in. Temperature was not a contraindication for transfusion; congenital syphillis with melena did not contraindicate transfusion, as was shown by the case cited. After comparison of methods in the new-born, he felt that many cases were lost by simple subcutaneous infusion of blood or serum which might have been saved by more radical methods, though in some emergencies the subcutaneous introduction of blood did well. The histories of such cases were related. Transfusion was uniformly successful in combating the hemorrhages in hemophilia in late infancy and childhood, even where much blood had been lost. In a bad case of anemia, very rare in childhood, two transfusions of 140 and 120 c.c. of citrated blood were initiated with improvement and recovery; the child was now four years old, and perfectly normal. In this case the hemoglobin was reduced as low as 15 per cent. at one time, and rose to 44 and 34 after each transfusion respectively. The spleen was enlarged, but after much consultation its removal was rejected. In acute diseases with tendency to hemorrhage transfusion was useful. Transfusion did not permanently benefit acute and chronic leucemia, and neither did it benefit purpuras of all varieties. Henoch's purpura was particularly rebellious to treatment. Transfusion was unsuccessfully used in several cases which had a low temperature with endocarditis crises due to an infectious encarditis. The hemoglobin index in these cases improved immediately after transfusion, but rapidly fell to the initial index, and the patient sank more quickly than one would expect had transfusion not taken place. There was one form of streptococcus invasion which by intensive and repeated transfusions might improve after the introduction of new blood, and this form of blood sepsis did not affect the heart itself. Eight repeated transfusions by the Lindemann method were used in one case of sinus thrombosis resulting from ear infection, and these held the patient over repeated crises, bringing recovery in spite of complications in the pleura and joints. In certain septic infections he had advised the removal of blood to make room for new blood in large quantity, thus avoiding the danger of overloading the circulation. In postinfluenzal nephritis cases the writer had transfused blood when the patient was fast sinking, and the urine showed blood. The transfusion caused not only a stoppage of bleeding but the nephritis recovered completely. Yet in similar cases many with the same trouble were transfused without success; the physician waited too long. Transfusion, performed in a rational way, might be a life-saving operation in a variety of infant and childhood conditions. Indiscriminate transfusion and its use as a last resort were impractical. There should be a very definite idea or indication to the performance of transfusion if the whole method of therapy were not to be brought into disrepute.

The Energy Metabolism of Children from Birth to Puberty.—Dr. Fritz B. Talbot of Boston presented a summary of the work done in the nutrition laboratory of the Carnegie Institution of Washington during the past three years on the metabolism of healthy children. In this study observations were made of 108 boys and 78 girls, ranging in age from birth to puberty. He stated that by basal metabolism was meant the minimum amount of calories a child could live on without allowing anything for growth. Up to 10 kilos weight, that was about one year of age, the basal metabolism of both boys and girls was the same. After that age the basal metabolism was a little higher for boys than for girls. The basal metabolism of women was below that of adult men. The curves seemed to show that some specific impulse was at work during puberty. All the food that went into an individual was not used. Some was lost through the feces and in other ways. It could be assumed that about 90 per cent. of food intake was available, and that was borne out by metabolic experiments. It had been shown that every movement a baby made consumed calories, and hence an increase over basal metabolism was caused by muscular exercise. On an average 25 per cent. of the food intake was used

in muscular exercise at six months of age. As the child grew older the amount of food used for growth became less and less. If the mother did not have sufficient milk for the individual baby, enough food was not left for growth after deducting the amount required for exercise and that lost in the feces. When a child had diarrhea or indigestion a greater amount of the food was lost in the feces than normally and less was left for growth. This loss might sometimes be as high as 40 per cent. of the food intake. Again, some children who were apparently getting a sufficient amount of food were overactive, and the food needed for growth was used up in the energy output.

Dr. L. Emmett Holt of New York, after congratulating Dr. Talbot on his valuable contribution, said that the paper had explained a great many of their common experiences, as, for instance, individual differences in children so far as their food requirements were concerned. They all knew that it was impossible to feed a baby according to its weight or age, and that a great many factors had to be taken into consideration before one could judge accurately how much food a child required. Dr. Talbot had put down in figures just how much value was to be attributed to each factor. For the first time this had been done in a scientific way. Muscular activity in relation to weight increase was very important, not only in infants but in older children. They frequently met children who, though apparently getting sufficient food, did not increase in weight until their muscular activity was decreased. Other children again might be getting three times as much food as they could take care of, and were having excessively large stools, and here the loss might be overlooked unless the stools were examined.

Postinfluenzal Encephalitis.—Dr. Henry Heiman of New York read this paper, which was based on a study of eight cases from the Pediatric Service of Mount Sinai Hospital. He stated that various terms had been suggested to designate this condition, none of which seemed entirely appropriate; he, therefore, suggested "postinfluenzal encephalitis," since one could not help being impressed by the close association of this symptom complex with epidemic influenza. The only periods during which it had been observed were the years following the extensive epidemics of influenza. As a result of his observations he had been able to differentiate three main forms, depending on the severity and the most prominent symptoms. These might be grouped as (1) irritable; (2) lethargic, and (3) lethargic with paralyses. The irritable type was characterized by marked restlessness, excitability, and almost continuous crying. In the lethargic form the most prevalent feature, as the name implied, was a drowsy state. The facial features were expressionless, mask-like, and resembled the Parkinson syndrome. There might be convulsions or twitchings of the face muscles. There was frequently moderate rigidity of the neck. Most of these cases fell into the third group of lethargy with paralyses. In addition to the stuporous state there might be involvement of the extremities or cranial nerve palsies. In the writer's series of cases the oldest child was 13½ years, and the youngest four months. The cases were equally divided between the sexes. In one child the nervous syndrome followed immediately, and in another four months had elapsed. The average time of onset of nervous symptoms was about two weeks after the attack of influenza. The onset of the encephalitis was sudden in six cases, while in two there was a progressive development. Convulsions were the first manifestation in three of the cases. Fever played a small rôle in all of the cases reported. The fundi were examined in all the cases of this series, but showed nothing characteristic. The cerebrospinal fluids were examined in these cases, but showed nothing abnormal. In one instance there were 80 cells per cubic centimeter, 80 per cent. of these being lymphocytes. In this instance albumin was present, and there was a definite reaction to Fehling's. There were no organisms. There were no uniform changes in the blood picture. The prognosis was better than the alarming state of the patients would indicate. Thus far they had not lost any cases, but in two, at least, the mentality had been definitely affected. There was no specific therapy. Their treatment had been symptomatic throughout. In the irritable type mixed bromides and chloral were of some value. In the paralytic type massage of the involved muscles was of distinct advantage. Lumbar puncture had been of no special benefit.

Dr. Henry Koplik of New York stated that they had all seen these cases throughout the epidemic in New York, and that the clinical features had been well described by Dr. Heiman. They were quite similar to the cases of poliomyelitis that had been described on both sides of the Atlantic, appearing to be of the hemorrhagic type that affected the brain and not the cord. Some of the lethargic cases resembled tuberculous meningitis, and some physicians had made the diagnosis of tuberculous meningitis in these cases, only to find at the end of a week or ten days that their patients were on the road to recovery. These patients did well without lumbar puncture. There were different types of encephalitis seen following the epidemic of influenza; all were not of the lethargic type.

Dr. Isaac Abt of Chicago called attention to the fact that all the cases of encephalitis they had been seeing were not due to influenza. Encephalitis might follow pneumonia, measles, typhoid fever, or whooping cough. The disease was selective, affecting certain portions of the brain, there being a certain number of cases in which the anterior motor areas were affected, and in some there was a one-sided paralysis. The prognosis was good so far as life was concerned, but a number of those affected remained paralyzed.

Dr. Richard M. Smith of Boston described a case of encephalitis in a child, 4½ months old, who, in addition to the symptoms mentioned, was still unable to cry a week after the onset of the disease. In this case the most striking feature was the contraction of the pupils.

Dr. Talbot of Boston asked Dr. Heiman if he had had any reports from adults as to whether double vision was among the early symptoms.

Dr. Heiman replied that he had not seen diplopia, but he had seen cases with ophthalmoplegia.

(*To be continued.*)

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held March 7, 1919.

Dr. Seth M. Milliken in the Chair.

Fused Kidney. Right Hydronephrosis. Resection. Recovery.—Dr. Martin Rehling presented this case, a man 52 years of age, who came under his care on July 10, 1918, complaining of dyspepsia and increasing constipation and vomiting. He was admitted to the hospital on August 7. He had never been sick except for a Neisserian infection many years ago. Physical examination showed a bulging mass in the right side of the abdomen extending far down into the pelvis continuous with the liver dullness above and then running off to the left side. There was a flatness on percussion and no sign of spleen or kidney could be made out. The prostate was slightly enlarged. The urine was normal and did not contain blood. Cystoscopic examination showed a deeply trabeculated bladder and the ureter on the right side could not be seen. The *x*-ray diagnosis was dilated colon, partial obstruction of splenic flexure, and enlarged and elongated appendix. At operation a right rectus incision was made which revealed an elongated mass reaching from the pelvis to the diaphragm. The colon collapsed in front of it. At the level of the umbilicus there was an extension of the tumor which reached beyond the vertebral column to the left. This mass was found to be a fused kidney, cystic on the right side—a horseshoe kidney with the concavity upward. One small strand was found which looked like a ureter. Some fluid escaped during the removal of this strand; the remaining sac contained about two liters of fluid. The right side containing the tumor was resected from the other side; there was no isthmus, the mass being continuous with the left part of the kidney. There was some spurting from one small artery in the remaining left part of kidney which was easily controlled by a transfixion suture. A small drain was inserted and the patient made an uneventful recovery. As he was doing well and the urinary output

was satisfactory no cystoscopic or phenolphthalein test had been made, as the patient was opposed thereto. A few similar cases have been reported in the literature and Rovsing has operated on several cases, removing the mass through the right rectus incision.

Dr. ROBERT T. MORRIS said it seemed to him that it was very important to determine whether the part of the kidney that was left had undergone compensatory hypertrophy and was continuing full function, because this was not only a case of hydronephrosis, but also of fused kidney. Patients with this latter condition often suffered a great deal of pain after middle life, because of the drag due to absence of Gerota's pouch. This drag might perhaps be relieved by dividing the fused kidney, but before this was done one should find out if a compensatory hypertrophy of the remaining part of a kidney would take up the work of the entire kidney. The danger of hemorrhage must also be considered in making a division of a fused kidney, and the question came up whether one could safely make a complete division through the middle of a fused kidney as a rule.

Dr. REHLING, in closing, said that the hydronephritic portion of the kidney in this case was not functioning at all. The fluid in this part of the kidney contained very few urinary elements. It was not likely after the man had reached the age of 52 years and the other kidney had for many years been doing the work of both kidneys that it would fail to do its work now. The pathologist's report showed that the part of the kidney removed was composed largely of embryonal structures and the kidney structures resected for the remaining left part of the fused kidney showed a slight degree of glomerular nephritis. The removed sac after emptying measured 30 by 18 cm. in diameter.

Complications and Sequelæ of War Wounds as Seen at United States Army General Hospital No. 1.—Lieut. Col. WALTER A. SHERWOOD, M.C., U. S. Army, read this paper, in which he said he would speak but briefly and of generalities. He discussed his subject briefly under the following headings: 1. Chronic infection of bones and joints. 2. Unhealed wounds of soft parts, including infected amputation stumps. 3. Deformities and disabilities due to malposition of bones and bony defects. 4. Deformities and disabilities due to destruction of soft parts (skin, fascia, muscles, and tendons). 5. Injuries of the brain, spinal cord, and peripheral nerves. 6. Wounds of the thorax, abdomen, and their contained viscera. 7. Miscellaneous. He considered Group One the most important of these because the problem there was often one of osteomyelitis, and experience had taught them to treat these cases conservatively and to defer operation for a considerable length of time except for the institution of proper drainage. When operation was indicated in this group of cases they made large funnel-shaped openings, removed all necrotic tissue, and employed the Carrel-Dakin treatment. In considering the second group of cases, the unhealed wounds of the soft parts, the speaker stated that one met unheard-of wounds of the soft parts, in which there was very extensive destruction of tissue. Strapping and heliotherapy had been particularly effective in dealing with this type of wound. The fourth group of cases, in which there was deformity and disability due to malposition of bones, often harbored latent infection and in cases in which bone grafting was necessary this procedure should be postponed for several months. In some of these cases the growth of bone was so rapid that later bone grafting operations could be dispensed with. In discussing the deformities due to destruction of the soft parts he considered more particularly tenoplasty. In speaking of injuries to the brain, spinal cord, and peripheral nerves he stated that but a small number of these cases were operable, about 5 per cent. A detailed report would later be made on each of these groups of cases. Col. Sherwood then showed a series of lantern slides to illustrate the various surgical problems with which the Army surgeons were at the present time confronted.

Col. CHARLES H. PECK said he felt a little embarrassed in attempting to open the discussion on this splendid presentation of Col. Sherwood's, because it furnished so much material for discussion that it would be impossible to cover it in a reasonable length of time. It would therefore only be possible to emphasize several points that stood out prominently. In the first place the slides brought to their attention the tremendously destructive character of these wounds inflicted by the missiles of modern warfare and had visualized in an excellent way the judgment and surgical skill that would be required to treat the thousands of battle wounds that must be cared for. It emphasized that the wounds were in most instances infected and that among these the cases suffering from osteomyelitis formed a large and important group, in fact the most important of all battle casualties. To speak in general terms of so many cases and of general problems of treatment, that of adequate drainage and the attempt to sterilize cases was most important, but it gave no adequate idea of the subject such as was conveyed by the visualization of individual cases. These pictures showed that many cases were deserving of papers in themselves, and that many features had to be considered in carrying a case to a successful conclusion and a restoration of function. Another point to be emphasized was that secondary operations should not be attempted too early. It was important to use the best judgment and to give plenty of time for an infection to quiet down before undertaking a secondary operation. It was true, however, that cases of osteomyelitis might require prompt opening and drainage. Bone cutting and grafting was attended with much danger if undertaken before infection had quieted down, and this was especially true if the infecting agent was a hemolytic streptococcus. In spite of all that they had learned during the four years of the war it was often difficult to avoid or overcome infection even when the cases were brought in early and complete débridement was done, and this was accomplished under actual military conditions in only a small percentage of cases. They had to deal with wounds not as they would like to have them, under ideal conditions, but frequently many hours after the wounds had been received and after the men had been lying out in shell holes or on the field. After the men were transported from the front line hospitals or to the base hospitals the conditions met with were the late results and sequelæ of infection. Since the beginning of the war they had had wonderful aid in the Carrel-Dakin treatment, which was probably the most valuable single addition to the former methods of treatment that they had. Carried out in the best way and in the best hospitals, it had been effective in a large percentage of cases in controlling infection and promoting healing. As it was being carried out in our own great military hospitals, where it was receiving its full measure of attention, it was giving very satisfactory results. In the cleaning up of large wounds of the soft parts Col. Sherwood had spoken of the use of a mild solution of boric acid and exposure to sunlight. That method had been tried by some of the military hospitals on the other side. Dr. Conner had tried it on the other side, and he believed that it was a principle worthy of extended trial. The whole section was indebted to Col. Sherwood for having visualized such a large number of battle casualties such as would have to be met and treated by the military surgeons of this country now and for many months to come.

Dr. CHARLES A. ELSBERG said he had been fortunate in seeing some injuries of the peripheral nervous system in soldiers and there were a few facts with which he had been impressed in these cases. In the first place, due to the fractures that occurred so often of the humerus, forearm and the femur and other bones of the lower extremities, the patients had to be immobilized in splints for a considerable period of time. Therefore it could not be avoided that there should be great stiffness in one or more joints without actual injury to the joint. When one attempted to make up his mind whether he was dealing with a nerve injury or not it was often impossible to do so. The joint would be stiff, the muscles were stiff, and there was considerable loss of sensation from wearing splints so that it was necessary first to give these patients physio-therapeutic treatment before one could really say whether or not a nerve injury existed. Therefore it was not surprising that many of these patients came without any mention of nerve injury because of the complicating injuries of bones and other tissues which made it impossible to say whether a nerve had been injured or not. All this showed the importance of proper physio-therapy and of the proper use of splints from the beginning of the

treatment. Another fact in regard to nerve injuries was in connection with a certain group of patients, who after four or five months showed no definite improvement in the functions of the nerves, and the question of the advisability of operative interference had to be considered. One should be careful in making the statement that all such cases required operation for every once in a while one would be surprised to see such a patient suddenly begin to improve. Dr. Elsberg cited such a case occurring in a man with a musculo-spiral paralysis. For months this man's condition remained stationary and finally, on January 10, they decided that he required operative interference, inasmuch as there was complete musculo-spiral paralysis, both motor and sensory. For certain reasons the operation was delayed for a week, and when he was examined at the end of the week it was found that he had considerable return of power and sensation which had appeared within the week, after five months of complete paralysis. Such cases made one cautious and more conservative than usual. At Army General Hospital No. 1 the speaker had supervision of the operating on nerve injuries, and they had found that only about 5 per cent. of nerve injuries in that hospital required operation. It was a great surprise to him to learn that in one Army hospital 50 per cent. of nerve injuries had been operated upon; in another one in every three cases, and in still another one in every four cases.

Dr. HAROLD NEUHOF referred to a few points in connection with the treatment of infected wounds at base hospitals. One of these was the question of amputation, which he said required much surgical judgment. At their base hospital in France they had many compound fractures of both the upper and lower extremities, and not a few infected knee joints, with and without bone involvement. In the beginning amputation was deferred too long in some of these cases; as a result such patients were no longer in condition to stand operation. Furthermore, autopsy in such cases would show widespread pyemic foci of infection arising from suppurative phlebitis of the venous trunk in the region of the infected wound. As a result of these experiences, they had gradually come to amputate earlier in these cases. They also frequently resorted to amputation in compound fracture when secondary hemorrhage developed. Conservative treatment frequently failed and it was found that infection of the accompanying vein was almost uniformly present in hemorrhage from one of the main arteries of an extremity. When amputation was not done, the vein was usually resected with the diseased artery in such instances. Every effort was made to be more conservative about amputation for infected compound fracture in the upper extremities, but here, too, it was unfortunately necessary to amputate in some cases, despite every effort to control infection, in order to save lives.

Dr. FRED H. ALBEE said his experience enabled him to bear out statements made by Dr. Elsberg in reference to neuro-surgical cases. At General Hospital No. 3 there were on his service 225 such cases. The cock up splint had been found very advantageous in the treatment of injuries of the musculo-spiral nerve. Its management, however, presented some difficulties. At the same time that the extensor muscle supplied by the musculo-spiral nerves were prevented from becoming overstretched by the dropping of the hand and the wrist, stiffening of the joints of the wrist and hand must be prevented by suitable physio-therapeutic treatment. During this treatment, however, the hand should never be allowed to drop into extreme flexion. He felt convinced that if the treatment suggested by Dr. Elsberg was religiously carried out that the operative interference in these cases would be much diminished. In regard to osteomyelitis of the bones, in a large percentage of cases, one had to be rather radical and not only remove all dead bone but also, on mechanical principles, all deep pockets and shelving projections of bone should be removed, as they led to the pocketing of the infection and the prevention of healing. It was important to study the *x*-rays, which helped to disclose deep pockets, dead bone, and foreign bodies. In their work they had been guided by the *x*-ray in determining whether they were dealing with osteomyelitis of any extent associated with the gunshot injury or not.

Dr. FENTON B. TURCK said Dr. Sherwood's paper was most valuable in that it had given them information on a wide variety of pathological conditions, both before and subsequent to treatment. Most important among the points he had brought out was that he had shown the importance of the part played by necrotic tissue in relation to wound disease and the advantage of increasing the resistance of the patient. At the Interallied Conference of Surgeons, held in 1918, Tuffier and Sacquepée (*Archives de Med. et de Pharm.*, Paris, 1918, XX, p. 613) analyzed their results in the primary, secondary, and late treatment of war wounds and the conclusions they reached were that sterilization by chemicals was defective and that necrotic tissue was the important factor in delaying healing. Therefore the method of treatment that gave the best results was wide débridement and rapid suture, thus eliminating the source of the poisons from the necrosed tissue, which were the cause of wound disease. Dr Turck cited other references to the literature of war surgery showing that surgeons were coming to the viewpoint that elimination of necrosed tissue and not the destruction of bacteria was the problem to be solved. The bacteria merely played the part of secondary invaders increasing the autolysis that was already going on in the tissues. From this standpoint sunlight as a treatment for wounds should be very beneficial since it overcame tissue autolysis, increased tissue resistance and speeded up natural antitoxin formation. This was also true of baking. Nature was always manufacturing these antitoxins against tissue necrosis and it was always an advantage to assist her in this process. Dr. Turck then referred to his experimental work and the antitoxin which he had been able to produce against tissue necrosis, and said that as they had been able by the use of autolyzed muscle tissue to produce an antitoxin against the necrosis of muscle tissue and by the use of autolyzed lung tissue had produced a specific antitoxin against necrosed lung tissue there was no reason why in time they might not be able to produce an antitoxin against osteomyelitis.

Dr. WILLIAM C. LUSK said he thought that the section might be interested in the work he had been doing in wound healing with the use of chinosol and salt. He had shown some of his cases before the New York Surgical Society. Among the results of wound healing by the use of these agents he cited the following examples: A case of cellulitis covering an area about the size of his hand, due to colon bacillus, with sloughing interior, in which with the use of a solution of 2 per cent chinosol and 5 per cent. sodium chloride the opposing surfaces of the abscess cavity were almost completely united on the ninth day; a case of two small areas of staphylococcus aureus cellulitis in the same patient, in which, with the use of the same solution, the opposing surfaces of the abscess cavities were largely united on the ninth day; small abscesses healed in about a week's time; an ulcer infected with pyocyaneus, in which, after a two-hour application of 2 per cent. chinosol and 5 per cent. salt, with subsequent dressing with sterile gauze, which was left in place for 48 hours, the green stain did not recur; a bone cavity about seven inches in length in an expanded lower portion of the shaft of a tibia, resulting from an operation for osteomyelitis, the whole medullary area of this portion of the bone having been removed, which, with daily applications of 2 per cent. chinosol and 0.6 per cent. salt for about two hours, became filled with granulations in the course of about five weeks, after which with the use of a chinosol ointment and strapping, the epithelium grew over the surface of the ulcer; a pelvic fistula six to eight inches in length, the opening of which was at the apex of a wound completely dividing the anal canal, with daily injections of 2 per cent. chinosol and 5 per cent. sodium chloride, in a month's time reduced to two and one-half inches in length, and later closed entirely, with irregular injections of chinosol and sodium chloride in alcohol; a deep wound entirely encompassing the anus, the result of the separation of a slough, with high retraction of the anus above the skin surfaces of the buttocks, which, with the daily application of a solution of 2 per cent. chinosol and 2 per cent sodium chloride for half an hour, cicatrized so that in three and one-half weeks' time the anus was pulled down even with the surrounding skin. He had obtained good results in the treatment of small abscesses and of a sloughing carbuncle with the use of a 2 per cent. chinosol in normal (0.85

per cent.) sodium chloride. The technique was simple, application of the chinosol-salt solution generally being made by means of gauze. He said he had performed a great many experiments on dogs with the view of proving the value of chinosol and salt as a first-aid disinfectant. For this purpose the chinosol should be used in combination with 0.85 per cent. sodium chloride. In the animal experiments the wounds were constructed as pockets between the superficial and deep layers of the superficial fascia on the dogs' backs. In a recent series consisting of 12 dogs, in which the lymphatics leading from pockets uncontaminated with blood were first infiltrated with about one ounce of the solution, the wounds then packed for fifteen minutes with gauze wet with the solution, then infected with as much of a virulent twenty-hour culture of staphylococcus aureus as could be absorbed on a piece of gauze about half an inch square crumpled up, which was left in the wound for half an hour, then treated again for fifteen minutes with a chinosol-salt solution applied on a gauze pack, and finally sutured up tight, these same wounds in seven of the animals united by primary union, while the controls all suppurated. The strengths of chinosol used in this series of animals were grains iv and grains vi to the ounce, and 2 per cent. He had presented a scientific treatise on the subject recently before the New York Surgical Society, which would soon appear in print.

Dr. JOHN F. CONNORS said that in their experience with war wounds there were many things that had come to them which were surprising, and one of these was that there was so little hemolytic streptococcus infection. Another point was that of amputations in osteomyelitis. At Savigny they had had more deaths following amputations than from anything else, and they came to realize that it was because they tried too long to save the limb. They first tried to control secondary hemorrhage by ligation and packing, but they found that they were losing many men, so they began making amputations earlier and they then found that more men lived. As to the treatment of wounds with sunlight and air, at Savigny they at first had some difficulty in getting the method employed, but after a short time when the results were demonstrated they had no difficulty at all. It was a simple method and appealed to him as strongly as anything he knew of. It was the best thing for late gas infection. A large number of such infections developed in the muscles of the back of the leg in men who were allowed to pass through the casualty clearing stations and evacuation hospitals, and when one came to operate on them he found them infected with the gas bacillis. These wounds were treated by opening them up widely and packing with peroxide of hydrogen at night, while during the day they were exposed to the sunlight. Many cases of late gas infection were saved by this means. The speaker emphasized that cases of osteomyelitis should be left alone until they saw what nature could do for them.

Col. SHERWOOD, in closing, said that he had purposely omitted the details of treatment and results, as he intended taking these up at a later time. He wished now to emphasize what Col. Peck had said in reference to the Carrel-Dakin technique. They were using it right along and expected to continue to use it. The cases in which it had failed were those in which it was applied by men not properly trained or not enthusiastic as to its value. The men who had had the course at the Rockefeller War Hospital and were enthusiastic got first-class results all the time.

Empyema at Base Hospital, Camp Mills, with Special Reference to the Use of Philips' Empyema Apparatus.—First Lieut. H. B. PHILIPS, M. C., U. S. Army, presented this communication, in which he first gave a brief résumé of a previous preliminary report on this subject published in *Surgery, Gynecology and Obstetrics*, in February, 1917. The apparatus consisted of a special cannula, a bottle, a negative pressure manometer, a suction pump, and connecting rubber tubing. The cannula was of special design so as to be used for a trochar cannula for the thoracotomy, and being also non-obstructible, it remained in the chest wall until the empyema sac was obliterated. A rubber suction pump surrounded the cannula and permitted of an absolutely air-tight connection with the pleural sac. This made it possible to empty the pleural sac with non-obstructible drainage, maintaining a continuous negative pressure of 30 to 60 mm. of mercury, until the empyema sac was obliterated and firm adhesions formed between the visceral and parietal pleura, when the apparatus might be removed. During the height of the epidemic of influenza only one apparatus was available, and it was only at the tail end of the series that enough apparatuses were on hand to meet the demand, so that it was necessary to resort to varied treatments, which, however, were all consistently conservative. For a clear consideration of these cases they were divided into four groups, as follows: 1. Those treated by simple repeated aspirations. 2. Those treated by intercostal drainage. 3. Those treated by rib resection drainage. 4. Those treated with the Philips apparatus. In the great majority of cases treated by simple aspiration this method failed and more radical treatment had to be instituted early. Of a group of 17 cases, three terminated successfully, without any other treatment except repeated aspiration. In most of these cases symptoms of aggravated sepsis or the appearance of pneumothorax, in spite of the most persistent care to prevent these complications, indicated better drainage methods. Their experience had led them to feel that the contraindications for repeated aspirations were the following: (1) the character of the exudate such that it obstructed the cannula or needle. (2) Absence of improvement following this treatment. (3) The appearance of a complicating pneumothorax following aspiration. (4) Severe toxemia of the patient. Ten cases were treated by intercostal drainage, two of which were healed in 43 and 45 days respectively. Two cases were transferred and lost sight of. There was a mortality of 30 per cent. in this group. At the time of writing this report three of the cases were draining over 70 days. All attempts to secure air-tight intercostal drainage with improvised cannulas met with absolutely no success. These cases all showed the disadvantages of open thorax in addition to those of inadequate drainage. Twelve cases were treated by rib resection. These cases were divided into those treated by repeated preliminary aspirations, and those in which the operation was the initial treatment. In the former group there were seven cases, with one mortality; in the latter group there were two cases completely cured in four weeks' time. The impression from this group of cases made one feel that the postponement of the operation, with repeated aspirations gave the patient an easier time with apparently less risk at the operation. However, it seemed to be an advantage paid for during convalescent time, for undoubtedly the delay permitted of the formation of adhesions in a partially collapsed lung, which enhanced the chronicity of the condition. Of the cases treated with Philips apparatus, 16 in number, the most prominent facts deducible were: (1) That complete expansion of the lung was secured in an average of three days after the application of the apparatus. (2) That the mortality of the straightforward cases of empyema, that was those not complicated by coincident active pneumonia, was *nil*. (3) A large pneumothorax was exceedingly improbable and not encountered in their experience, and the open pneumothorax was impossible after the apparatus had been applied only a few days, for by this time the lung had been very considerably expanded and a good part of it had become adherent to the chest wall in its expanded condition. (4) That the duration of the empyema as such was very materially shortened. The writer described the advantages secured by the apparatus in detail and summarized them by stating that they consisted in the following: (1) The exclusion of atmospheric pressure. (2) The necessity for operation was done away with entirely. (3) The exclusion of secondary infection. (4) The duration both of the treatment and the condition was very materially shortened. (5) A functionating lung was secured from the very start. (6) The apparatus provided a clean, sanitary, pleasing and economical way of getting rid of the pus. During the entire application of the apparatus, the dressings remained perfectly clean, as when originally applied. Adhesive paste interspersed between the layers of the dressing made an ideal air-tight dressing which did not leak. Attention was called to the fact that the apparatus could be used with success in ordinary serous pleural effusions. The danger

of secondary infection was minimal, and the means afforded of expanding a chronically compressed and collapsed lung by the apparatus could not be overlooked.

Major CHARLES L. MIX said he was pleased that the section had had the opportunity of seeing these *x*-ray plates, else they might not have a clear idea of the curative effects of Lieut. Philips apparatus in cases of empyema. Their early experience at the Base Hospital at Camp Mills had been about the same as that of other hospitals in that the mortality last April in their cases of empyema was 55.5 per cent., all of the cases being caused by the *Streptococcus hemolyticus*. During the recent epidemic of influenza they had had unusual opportunities for the study of empyema following the pneumonitis of influenza, and also that following true lobar and bronchopneumonia. Major Mix reported the detailed statistics of these cases for two week periods from September 14 to November 15, during which period they had 3911 cases of influenza. Of these 1048 developed pneumonia and 394 died. Of the 1048 pneumonic cases 60 developed empyema, that is to say fluid in the pleural cavity, even though it were merely turbid fluid and not purulent. Of these 60 cases 16 died, and of these 16 only eight were in the hospital more than 21 days. In other words, 8 of the 16 did not die of empyema, but of pneumonia, and should not be charged to empyema deaths. If one took these 8 cases from the 60, it left but 52 cases of empyema, with eight deaths, which was a very respectable statistical showing.

As to their methods of treating empyema, they had first followed the recommendations of the surgeon-general's office and had employed repeated aspiration, but there was no one so skillful that he could repeatedly aspirate a patient without producing a pneumothorax, and the reason these cases of repeated aspiration did not all get well was because of secondary infections due to this "external" pneumothorax. Therefore repeated aspiration was not the best or the ideal treatment for empyema. There would always be some cases in which rib resection would be indicated, but this method of treatment was open to the great objection that it invariably produced pneumothorax, and that subsequently the lung expanded very slowly over a long period of time. Though rib resection was safe and the results good in many instances, yet the convalescence was a matter not of weeks, but of months, and all have seen instances in which the sinus remained open for years.

Dr. Philips' apparatus was simple, and with it one could secure complete negative pressure and continuous sucking out of pus without any chance of air getting into the pleural cavity. The lung expanded and stayed expanded, so that there was no accumulation of pus or fluid. There would of course remain as a sequel a sinus around the trochar, but this healed in a few days without danger to the patient. The advantages of the method were very great. There were no wet dressings which were malodorous, sticky and uncomfortable; one had instead of dressings saturated with pus nothing but a passage-way out from the chest to the bottle, and no germs could get into the chest. This method was of fairly general application, and was of a great deal of value except in cases falling into certain categories. Cases in which it was not applicable were those of "internal" pneumothorax in which air escaped from a bronchus into the pleural cavitiy, because the apparatus would merely suck air through a bronchus into the bottle so that drainage could not be maintained, but in such cases the apparatus was of value as a diagnostic means since it quickly demonstrated the existence of an "internal" pneumothorax because of inability to create a negative pressure. A second group of cases which were unsuitable for this treatment were such cases of *Streptococcus hemolyticus* infection as showed intense toxemia; these did not get well with any treatment. In such cases with low systolic and diastolic blood pressure and a rapid pulse-rate even rib-resection was of no avail. A third group of cases in which the apparatus might not be applicable were those with multiple pockets of pus. It would sometimes be found that the apparatus could not reach all the pockets, and therefore in such cases one might be obliged to resort to rib-resection. Aside from these three classes of cases the apparatus certainly did work wonders, and did lessen mortality; moreover, it shortened convalescence and lessened the septic absorption..

Capt. H. A. JOHNSON stated that Lieut. Philips' apparatus contained a number of elements which led him to believe that it was important in the treatment of empyema. It was clean and maintained negative pressure accompanied by expansion of the lung. In Portland they had attempted the same thing, and their results were as satisfactory as at Base Hospital No. 1. This method was a compromise between rib-resection and aspiration, and was useful in cases in which the patient might not be a good risk for rib-resection, though in such cases rib-resection might be done under local anesthesia. He had done rib-resections under general anesthesia for empyema, both acute and secondary, following lobar and bronchopneumonia and wounds of the chest without any deaths, and he had resected from one to four ribs, but these operations might have been done under local anesthesia. Captain Johnson said that in his opinion surgical judgment was far more important than surgical skill in dealing with pus in the pleural cavity, and he believed that rib-resection could be done under local anesthesia without shock, the patients not complaining of pain. The operation was followed by the use of free drainage, two to four No. 10 Carrel tubes being employed, and in no case had there been a resulting pneumothorax. It was not an ideal procedure on account of the difficulty of sterilization, but they had used it and had a clean ward and very little pus. There was one objection to rib-resection, and that was osteomyelitis of the rib and secondary necrosis, which demanded future operative interference. He believed, however, that rib resection was desirable and that no good drainage could be maintained without it.

Dr. FENTON B. TURCK described animal experiments which he was carrying out in which by insufflation into the tracheas of cats a pneumonitis was produced within two hours which killed the cats. This had been accomplished by using six drops of a 50 per cent. solution of 48-hour emulsion of autolyzed lung tissue. There was no reaction until the emulsion reached the lungs of the animals, thus showing its specificity. In other experiments he had sprayed the feet of cats with this emulsion and had placed them with other cats, and all the animals who were exposed to this autolyzed lung tissue came down with pneumonitis, showing the same reaction. Dr. Turck also described the way in which he had injected a goat with this emulsion at intervals during a period of six months and had thereby secured an antitoxin against pneumonitis. He had made a study of the pathological changes taking place in this form of pneumonitis and felt confident that the antitoxin would prove effective against pneumonia. All this experimental work had confirmed him in the belief that the cellular necrotic changes, and not the pneumococcus or other bacterial invaders, were the real cause of pneumonia.

Dr. SETH M. MILLIKEN said he did not like to have the audience go away thinking that the intercostal incision with drainage in empyema cases was not of great value. He had seen a number of cases of empyema, particularly in children where the intercostal drainage was curative. In a series of eleven cases who were treated in this way no further treatment was necessary in six, while five had secondary rib-resection. Of course the intercostal drainage might not be effective where there was a pocket below the level of the drain. Of osteomyelitis of the rib following resection, he had seen but one case. In that the subperiosteal resection had been done.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

UNIVERSITY OF THE STATE OF NEW YORK.

New York, May, 1919.

(*Continued from page* 995.)

SURGERY.

1. Describe gangrene due to gas bacilli.
2. Describe a lymphangitis due to infection of the thumb.

3. Give the treatment of a penetrating bullet wound of the skull.
4. State the conditions of a breast cancer when operation is inadvisable.
5. Describe tuberculous arthritis before the stage of softening and give the surgical treatment.
6. State which lymphatic glands are primarily affected in each of the following and give the clinical appearance of the glands in each case: (*a*) epithelioma of tip of tongue, (*b*) streptococcic infection of index finger, (*c*) chancre of penis.
7. Give the steps of the operation of tracheotomy.
8. What is ranula? Give the treatment of ranula.
9. What is the surgical treatment of a moderate-sized osteosarcoma of the tibia?
10. State the causes of nonunion in fractures.
11. Name conditions that may simulate acute appendicitis.
12. Describe convergent strabismus and give its surgical treatment.

OBSTETRICS AND GYNECOLOGY.

1. What are the signs and symptoms of threatened eclampsia? State the urinary findings in threatened eclampsia.
2. Describe the technique of Braxton Hicks' internal podalic version.
3. What is a funnel-shaped pelvis? What diameters would suggest this condition?
4. Mention two causes of tonic contraction of the uterus.
5. What are the findings in a threatened spontaneous rupture of the uterus during labor?
6. Define phlegmasia alba dolens. Give its etiology and its treatment.
7. When should menstruation cease and what conditions may attend its cessation?
8. Name the diseases of the external organs of generation.
9. Describe an operative method to correct posterior displacement.
10. Make a diagnosis of pregnancy.
11. What conditions should be differentiated from chronic uterine inversion?
12. Give the measurements of the normal female pelvis.

HYGIENE AND SANITATION.

1. Describe in detail the principle involved in the tuberculin test in cattle and explain its application in public health work.
2. What purpose is served by the use of the Binet-Simon test?
3. Name the methods used for the wholesome preservation of milk.
4. How does the introduction of heat into a room assist in the ventilation?
5. Describe an effective sanitary method of caring for waste water from a kitchen sink in a farmhouse.
6. How may the spread of disease by the housefly be prevented?
7. How may the presence of diphtheria in a hospital for children be minimized?
8. What is meant by mechanical filtration as applied to a municipal water supply?
9. Describe the use of the antityphoid bacterine.
10. What purposes are served by open-air schools?
11. What are the best methods for the disposal of human excrement in a military camp?
12. What are the principles to be observed in the construction of a modern hospital for contagious diseases?

ANSWERS.

SURGERY.

1. *Gangrene due to gas bacilli* is a severe infection due to the extensive invasion of tissues by anerobic bacteria. The muscles are mainly involved, and in severe cases whole groups of muscles are affected throughout their entire extent. Contributing factors are the presence of a mixed infection or of extravasated blood and secretions from wounds, interference with the circulation, and dead or devitalized muscle tissue. There may be cellulitis or a localized gangrene or a gangrene of the entire limb. The characteristic symptoms of the last form are: Sudden, sharp, lancinating pain in the limb, below the wound; obliteration of the distal pulse; profound toxemia, with high temperature and rapid, low-tension pulse; characteristic fecal-like odor around the wound; the subcutaneous tissues are filled with lymph-like fluid containing bubbles of gas; the intermuscular septa and muscle sheaths are similarly filled with fluid and gas, and there is often separation between sheath and muscle tissue. —(From De Tarnowsky's *Military Surgery*.)

2. In *lymphangitis due to infection of the thumb* the line of lymphatic vessels is painful and tender, and surrounded with an area of edema. The nearest glands are swollen and painful (in this case the epitrochlear gland is involved); and, in suppurating cases, fluctuation may be made out. If the superficial vessels are affected, they stand out as red lines in the skin, and sometimes may be felt as cords. Inflammation of the deep lymphatics is diagnosed by edema, along with enlargement and tenderness of the glands. Constitutional signs of inflammatory fever are present, and vary with extent and virulence of the irritation.

3. *Treatment of a penetrating bullet wound of the skull:* "In all cases of punctured or compound depressed fracture a thorough exploration of the wound should be made, and all depressed or injured bone removed. Foreign bodies should be taken away, if found close to the wound; but it is doubtful whether a bullet should be sought for if it has penetrated deeply into the brain, or if it has traversed the brain and fractured the bone on the other side. Probably an aseptic incision, with removal of the splintered fragments and a limited search for the bullet is the best treatment to adopt, and, even if unsuccessful, will do but little harm if the patient's general state warrants an operation. Protruding brain tissue is gently removed, and the whole wound thoroughly purified with carbolic lotion; even the 1 in 20 solution may be used without fear. The dura mater should, if possible, be drawn together by one or two sutures, and a small drain tube or gauze wick inserted within it. It is often advisable to introduce a portion of sterilized gold foil between the cortex and the dura, so as to prevent the formation of adhesions. The scalp wound is closed, except at the drain opening; the gauze or tube should be removed, if all is going well, in about two days' time. If the temperature rises as a result of septic infection, the wound must be reopened and every effort made to relieve tension and thus localize the mischief."—(Rose and Carless' *Surgery*.)

4. *Conditions in which operation for cancer of the breast is inadvisable:* When the cancerous mass is fixed to the bony thorax; when there is extensive involvement of the skin, either by scattered nodules or by general infiltration; when metastatic growths have extended to the viscera; when the axillary involvement is very extensive; when there is extensive involvement of the supraclavicular glands; when there is marked edema of the arm of the affected side.

5. TUBERCULOUS ARTHRITIS —*Symptoms:* "In the early stages the signs are not at all well marked, especially in those where the primary stage is osseous, and consist of slight aching after use. Soon, however, the cardinal signs appear: (1) Increased heat over the joint; (2) the presence of some fluid in the joint; (3) impaired mobility; (4) wasting of the muscles which move the joint. The joint is usually maintained in the position of ease, viz., slightly flexed. In the late stages abscesses form, and the pain becomes severe, even to 'starting pains' at night. If the abscesses burst and are allowed to become septic, a hectic temperature follows, and amyloid degeneration may lead to death from exhaustion. The joint itself may be disorganized, the relaxation of the ligaments allowing dislocation to occur.

Results: "1. The disease may be cured, leaving a movable joint if treated early. 2. A cure may terminate in ankylosis if the articular surfaces have been damaged. 3. If sepsis has been admitted, the patient may recover after a time, with ankylosis and deformity; but as a rule, unless treated, death occurs from amyloid degeneration. 4. General tuberculosis may bring about a fatal termination.

"The *prognosis* depends on the stage at which treatment is begun, and whether the patient can afford good

feeding, sunshine, and fresh air for prolonged periods. Babies and old people are the worst subjects, so that for them conservative treatment is not advisable.

"*Operative measures:* Abscesses outside the joint should be incised, scraped out, and stitched up. Where the disease progresses in spite of expectant treatment, three operations are open to employment: arthrectomy, excision, and amputation. *Arthrectomy* means removal of the whole of the tuberculous material with as little disturbance as possible of the surrounding healthy parts. The joint is opened, the entire synovial membrane dissected out, and diseased areas in the bone gouged away. The joint will often be a stiff one, but the growing ends of the bones are not interfered with. *Excision:* The synovial membrane must be removed as in arthrectomy. The ends of the bones are sawn off and all the cartilage-covered surfaces removed. Bony union is obtained between the sawn surfaces. The choice between excision and arthrectomy depends mainly upon three things: 1. *The chance of successfully eradicating the disease* is greater with excision than with arthrectomy. 2. *The ultimate utility of the limb* is greater after arthrectomy in such joints as those of the upper extremity, ankle, and hip, if some movement is left; while in the knee a firm leg after excision is better than a weakly ankylosed joint after arthrectomy. 3. *The subsequent development of the limb* is stopped by excision, and not by arthrectomy, so that excision should not be done till after the sixteenth or eighteenth year. Infants and old people stand excision badly, from having insufficient recuperative powers. Infants should have arthrotomy or arthrectomy done; old people, amputation. *Amputation* is indicated in old or broken-down people; where there is extensive disease of the bone and soft tissues; where amyloid disease is advanced; where excision has failed, or sepsis is present as well as tubercle."—(*Aids to Surgery.*)

6. (*a*) In *epithelioma of the tip of the tongue*, the submental glands are primarily affected; (*b*) in *infection of the index finger*, the epicondyloid and axillary glands are affected; (*c*) in *chancre of the penis*, the inguinal glands are involved.

In (*a*), the glands become enlarged, cystic, and may ulcerate. In (*b*), the glands become enlarged, hyperemic, redder and firmer than usual, more tender, and may suppurate. In (*c*), the glands become enlarged, move freely under the skin, feel hard and shotty, and do not suppurate unless there is a mixed infection.

7. *Tracheotomy:* "The patient is placed on the back with a narrow pillow under the neck. Chloroform or cocaine can be used as anesthetics. An incision, 1½ inches long, is made downward from the cricoid cartilage, keeping strictly in the mid-line. The incision is deepened till the tracheal rings and isthmus are exposed. Enlarged veins give trouble during this stage if there is dyspnea. A director-hook is thrust into the trachea, and the point of a knife is slid along the groove to open the treachea from below upward. The patient is allowed to cough for a few minutes while the wound is kept open with dilating forceps; then the tube is tied in."—(*Aids to Surgery.*)

8. *Ranula:* "The term ranula is applied to any cystic tumor formed in connection with the glands in the floor of the mouth. Formerly these tumors were believed to be retention cysts due to blocking of the salivary ducts. They are now known to be the result of a cystic degeneration of one or other of the secreting glands in the floor of the mouth. The *sublingual ranula* is the most common variety. It appears as a painless, smooth, tense, globular swelling of a bluish color. It usually lies on one side of the frenum, and over it the mucous membrane moves freely. As it increases in size it gradually pushes the tongue toward the roof of the mouth, and so causes interference with speech, mastication, and swallowing. It is differentiated from a retention cyst of the submaxillary gland by the fact that a probe can usually be passed along Wharton's duct alongside of the swelling. The *treatment* consists in making an incision through the mucous membrane over the swelling, dissecting away the whole of the cyst wall if posible, and, if any portion cannot be removed, swabbing it with a solution of chloride of zinc (40 grains to the ounce), after which the cavity is stuffed with iodoform gauze and allowed to close by granulation. It is sometimes found more satisfactory to dissect out the cyst through an incision below the jaw."—(Thomson and Miles' *Manual of Surgery.*)

9. "The *treatment of osteosarcoma* is eminently unsatisfactory, as even though the most radical measures are taken, recurrence is too frequently observed, or death from secondary deposits occurs in spite of a successful issue locally. . . . Formerly, the rule that governed surgical practice was to amputate the limb well above the growth in all cases, and to ascertain by microscopic examination of the medulla at the time that it was free from disease. Thus for a tumor at the lower end of the tibia, amputation through the knee would be practised; if the upper end of the tibia is involved, amputation through the middle of the thigh. . . . The results of such treatment have been so bad, and dissemination of the growth to the lungs so constant, that surgeons are now doubting the desirability of such mutilating procedures, and trusting rather to the effects of local excision, where feasible, followed by treatment with radium, *x*-rays, or Coley's fluid."—(From Rose and Carless' *Surgery.*)

10. *Nonunion of fracture is caused by:* Ill health, want of approximation of the end of the bone, want of blood supply in the bone, defective innervation of the bone, disease of the bone, lack of rest, and immobility.

11. *Conditions that may simulate acute appendicitis:* Acute peritonitis, ovaritis, salpingitis, ovarian neuralgia, ruptured ectopic gestation, movable kidney with Dietl's crises, renal colic, nephrolithiasis, biliary colic, acute intestinal obstruction, cholecystitis, acute pancreatitis, gastric or duodenal ulcer, typhoid fever, colitis, enteritis.

12. In *convergent strabismus*, "there is deviation inward of the visual line of one eye. It is generally associated with hyperopia, with or without hyperopic astigmatism. It usually commences in early life, between the first and fourth years, when the child begins to use his accommodation for near objects, such as toys and pictures; rarely it is congenital. At first the squint may be noticed only at times (periodic), with near vision, or when there is any interference with the general health; but it is apt to become constant for both near and distant vision; occasionally it disappears.

Surgical treatment. Tenotomy of an internal rectus and advancement of an external rectus are employed either singly or in combination. *Tenotomy of internal rectus:* "The speculum is introduced and the eyeball drawn outward, if necessary, by an assistant. The conjunctiva over the lowest portion of the insertion of the muscle, together with the subconjunctival tissue aud Tenon's capsule, is seized with a pair of fixation forceps, raised and divided with scissors; the first cut divides the conjunctiva, the second Tenon's capsule. Keeping the fold raised with the forceps, a strabismus hook is introduced through the opening, passed beneath the tendon, and pushed upward until its point is seen through the conjunctiva at the upper border of the muscle. The hook is transferred to the left hand and raised so as to lift the tendon. The scissors are taken in the right hand and introduced, one branch between the tendon and conjunctiva, and the other between the tendon and sclera; the tendon is divided close to the sclera by two or more small cuts. The hook is reintroduced to make sure that no portion of the tendon has been left undivided. If the tendon has been completely divided, the hook can be advanced to the cornea without resistance; if not, the undivided fibers must be cut with scissors. The hook is again introduced and swept from behind forward, above, and below, to ascertain whether there are any uncut fibers of attachment to the sclera which, if found, must be severed. The conjunctival wound is closed with a single vertical suture."—(May's *Diseases of the Eye.*)

OBSTETRICS AND GYNECOLOGY.

1. *Signs and symptoms of threatened eclampsia:* Headache, nausea, and vomiting, epigastric pain, vertigo, ringing in the ears, flashes of light or darkness, double vision, blindness, deafness, mental disturbance, defective memory, somnolence; symptoms easily explained by the circulation of toxic blood through the nerve centers. These may be preceded by lassitude, and accompanied by constipation, or by diarrhea. Headache is perhaps the most significant and common warning symptom. In bad cases the urine is reduced in

quantity (almost suppressed), very dark in color, its albumin greatly increased, so that it becomes solid on boiling. Next comes the final catastrophe of convulsions.

The urinary findings in threatened eclampsia are variable; as a rule there will be found great diminution in the quantity excreted, diminution in the amount of urea, albumin is present in variable amounts, and there may be casts (hyaline, granular, etc.).

2. *Braxton Hicks' internal podalic version:* "The patient should be placed in the lithotomy position and be deeply anesthetized, to relax the parts and allow the whole hand to be pushed into the vagina. The external hand is placed over the breech, so as to depress it; while the presenting part is tilted away from the brim by the fingers inserted through the os. The fingers press against the front of the child and the flexion is lessened. When the head is out of the brim the external hand can be used to elevate it toward the fundus. As soon as a knee or foot comes within reach of the internal fingers, it should be caught and brought into the brim, the membrane being ruptured at the same time. If the os is fully dilated, delivery may be finished at once, as in an ordinary breech case; but if the os is only partially dilated, it must be left to nature, to allow of dilatation."—(Jardine's *Delayed and Complicated Labor.*)

3. *A funnel-shaped pelvis* has a contracted outlet, and is deeper than normal. At the outlet, the transverse diameter is always less than normal and often the anteroposterior diameter is also less than normal. The sacrum is narrow, situated far back, has lost its normal curve and is therefore longer; the lateral walls of the pelvis and the symphysis pubis are deeper than usual.

A pelvis may be considered "funnel-shaped" when the transverse diameter at the outlet is reduced from the normal of eleven centimeters to eight centimeters or less, and the anteroposterior diameter at the outlet is reduced to nine centimeters or less.

4. *Two causes of tonic contraction of the uterus:* (1) Anything obstructing the advance of the presenting part; (2) the premature and improper use of ergot.

5. *The findings in a threatened spontaneous rupture of the uterus during labor,* are: Evidence of some obstruction to the presenting part; the patient is restless and anxious, with rise of temperature and increased pulse rate; the pains are more frequent and stronger than usual, and one pain tends to pass into the succeeding pain without any interval; the lower part of the abdomen is unduly sensitive to pressure; the round ligaments become more tense; the uterus becomes retracted, and the retraction ring is more prominent and higher than usual.

6. PHLEGMASIA ALBA DOLENS is a form of puerperal sepsis in which there is a thrombosis of the iliac or femoral vein. Sometimes it occurs after a uterine phlebitis, in which clots are carried from the uterine sinuses to the hypogastric veins, where they cause obstruction to the blood flow in the crural veins. The trouble may also begin as a crural phlebitis. It is thus due either to cellulitis or to thrombosis. It usually appears about the third or fourth week of the puerperium. *Symptoms:* Irregular chilliness and malaise, pain in leg and abdomen, rigor and swelling of leg, fever, skin is white and tense, and the vein feels hard. *Treatment:* Rest in bed, support of the patient's strength, relief of the pain, and application of lead and opium wash to take down the inflammation.

7. Menstruation normally ceases at a variable time between the fortieth and fiftieth years. The symptoms of the menopause are referable to two stages: a stage of menstrual irregularity preceding the cessation of the menses, and a post-cessation stage of variable systemic disturbances. In normal or nearly normal cases the irregularities are not excessive; the systemic disturbances are slight. There is a period of unstable equilibrium. The woman may at times be unusually capricious and emotional; yet she passes through this physiological crisis with only a few minor disturbances. She may have the characteristic vasomotor flushes, perspiration, vertigo, somnolence, numbness, and faintness. The menstrual function ceases as it began, and other psychic disturbances are common in the abnormal cases, and may be exaggerated. The menstrual deviations vary in wide limits. The flow may gradually decrease and come at lengthening intervals until it altogether ceases; it may occur at short intervals or become continuous; it may become so excessive as almost to amount to dangerous hemorrhage; or life may be jeopardized by a slow, continuous drain. There is an increased tendency to malignant disease of the uterus and breasts during this period. The excessive fear of this may prey injuriously on the mind of the woman.—(From Dudley's *Gynecology.*)

8. *Diseases of the external organs of generation:* Vulvitis (simple and gonorrheal); erysipelas, abscess, varicose veins, hematoma, edema, gangrene, tumors, eczema, herpes, syphilis, tuberculosis, condylomata, elephantiasis, kraurosis, and congestion of the vulva; chancroids; urethral caruncle; inflammation and adhesions of clitoris; cysts of Bartholin's glands; inflammations, infections, tumors and cysts of the vagina; vaginismus.

9. *For backward displacements of uterus: Alexander's operation,* which consists of extraperitoneal shortening of the round ligament in the inguinal canal. The essentional points are aseptic and antiseptic precautions, to expose the aponeurosis of the external oblique, secure bleeding points, open the inguinal canal, isolate the round ligament and clear it of fat and cellular tissue, pull on the ligament till the uterus is far enough forward, and then cover the wound with a sterile pad while the opposite side is being treated similarly; both ligaments are then pulled tense, drawn across the symphysis, and stitched with catgut into the inguinal canal. Each stitch is passed through the skin and subcutaneous fat, then through the floor of the exposed canal, then through the round ligament, then through the opposite wall of the canal, and out through the skin. The ligament is stitched into the whole length of the canal, and the excess of ligament is cut off. The wound is then closed, the patient kept in bed for about three weeks, and in some cases a pessary is inserted for a month or six weeks. This operation is only available in the absence of adhesions, inflammations, prolapse, tumors, or pelvic diseases; that is, in uncomplicated cases of backward displacement.

10. *Positive signs of pregnancy:* (1) Hearing the fetal heart sound; (2) active movement of the fetus; (3) ballottement; (4) outlining the fetus in whole or part by palpation; and (5) the umbilical or funic souffle. *Doubtful signs of pregnancy:* (1) Progressive enlargement of the uterus; (2) Hegar's sign; (3) Braxton Hick's sign; (4) uterine murmur; (5) cessation of menstruation; (6) changes in the breasts; (7) discoloration of the vagina and cervix; (8) pigmentation and striæ; (9) morning sickness. *Subjective signs of pregnancy,* in the order of their appearance, are: Cessation of menstruation, morning sickness, increased frequency of urination, active fetal movements. *Objective signs of pregnancy,* in the order of their appearance, are: Softening of the cervix, changes in the mammary glands, discoloration of the vulva and vagina, pulsation in the vaginal vault, Hegar's sign, active fetal movements, ballottement, palpation of the fetus, intermittent uterine contractions, hearing the fetal heartbeat, rate of growth of the uterine tumor.

11. *Conditions which should be differentiated from chronic uterine inversion:* Uterine polypus or myoma, and prolapsed uterus.

12. Measurements of the diameters of the normal female pelvis:

	ANTERO-POSTERIOR.	OBLIQUE.	TRANSVERSE.
Brim	4 inches	4½ inches	5 inches
Mid-plane	4½ inches	4½ inches	4½ inches
Outlet	5 inches	4½ inches	4 inches

Between anterior spines ..... 10¼ inches
Between the highest points of the iliac crests 11 inches
Between trochanters ..... 12¼ inches

HYGIENE AND SANITATION.

1. "The mechanism of the tuberculin reaction, so far as understood, is as follows: The tuberculin acts as a local specific irritant upon the tuberculous foci, producing intense hyperemia and disintegration of the tuberculous mass. This phenomenon has been interpreted as an acceleration of a process going on more slowly under ordinary conditions, and is regarded as due to

the intensifying or stimulating action of the poisonous nucleoprotein, which is the essential ingredient of tuberculin. The disintegration is accompanied by the generation or liberation of toxic substances which enter into the general circulation and produce fever and other constitutional disturbances. The tuberculin reaction is not absolutely specific, but can be produced by various nucleoproteins, yeast nuclein, bacterial proteins, and other substances. Insusceptibility to the tuberculin reaction can be produced by repeated doses, a fact that has been taken advantage of by unscrupulous cattle dealers.

"When a small amount of tuberculin is injected into a healthy animal, there is no apparent constitutional disturbance; but when the same quantity is inoculated into an animal with tuberculous lesions, a remarkable selective action appears. There is marked congestion around the tuberculous area, accompanied by necrosis and sloughing off of the tuberculous tissue; fever and other constitutional symptoms also appear."—(Jordan's *Bacteriology.*)

"In cattle, tuberculosis may be present without any very apparent symptoms until an advanced stage is reached. Routine examination of herds by the tuberculin test has therefore become one of the necessary measures in public sanitation, in order that the milk of tuberculous cows may be excluded from consumption, and that such cows may be eliminated from herds (Bang's System). Mohler states that an accurate diagnosis is established in 97 per cent. of the cases. Stall the animal and take the temperature in the rectum every two hours from 6 A. M. until midnight. Make the injection then (subcutaneously). Begin to take the temperature at 6 A. M. and continue as on the preceding day. The dose is usually 0.25 c.c. of old tuberculin. A positive reaction consists in febrile and constitutional signs, with marked congestion around any focus of tuberculosis. The febrile reaction begins six to ten hours after injection, reaches its height in nine to fifteen hours, and declines to normal in eighteen to twenty-six hours. A rise of 2° F. or more above the maximum of the previous day should be regarded as a positive reaction. In a doubtful case, repeat in four to six weeks. (Normal rectal temperature, 100° to 102° F.; normal pulse, 45 to 55 beats per minute.)"—McKail's *Public Health Chemistry and Bacteriology.*)

2. The *Binet-Simon test* is employed to test the mentality of children and feebleminded persons.

3. *Essentials for the production and preservation of pure dairy milk:* Vaughan's rules are as follows: "(1) The cows should be healthy, and the milk of any animal which seems indisposed should not be mixed with that from the healthy animals. (2) Cows must not be fed upon swill or the refuse from breweries or glucose factories, or upon any other fermented food. (3) Milch cows must not be allowed to drink from stagnant pools, but must have access to fresh, pure water. (4) The pasture must be freed from noxious weeds, and the barn and yard must be kept clean. (5) The udders should be washed and then wiped dry before each milking. (6) The milk must be at once thoroughly cooled. This is best done in the summer by placing the milk can in a tank of cold water or ice water, the water being of the same depth as the milk in the can. It would be well if the water in the tank could be kept flowing, and this will be necessary unless ice water is used. The tank should be thoroughly cleaned each day, to prevent bad odors. The can should remain uncovered during the cooling, and the milk should be gently stirred. The temperature should be reduced to 60° F., or lower, within an hour. The can should remain in cold water till ready for delivery. (7) Milk should be delivered, during the summer, in refrigerated cans or in bottles about which ice is packed during transportation. (8) When received by the consumer, it must be kept in a clean place, and at a temperature some degrees below 60° F."

4. "Air when heated becomes lighter and more bulky; when cooler it becomes heavier and less in bulk. Hot air tends to rise and cold air to fall; as a result currents are created, all of them setting from the colder surfaces to the warmer and back again, and so keeping up a more or less continuous circulation. The heated, lighter, more bulky air, seeking greater accommodation, tries to escape from the space in which it is contained. In a room it makes for the outlets, and if these are in the upper parts of the space the air makes its way through them. To take up the space vacated by the escaping air, new fresh air enters at the inlets, and ventilation or carrying through of air is brought about. The heat affecting the air in a room is obtained partly from the occupants of the room, partly from the heating and the illuminating apparatus. The cold that affects the air and leads to its contraction and increase in weight, and incidentally also to its circulation, is derived from windows, walls, and doors."—(Porter's *Hygiene and Public Health.*)

5. *Waste water from a kitchen sink in a farm house* may be collected in the kitchen and then poured into a remote part of the yard or some field, first using one site and then another, care being taken that the water has an opportunity to soak in; this method is not available when the ground is frozen. Or it may be emptied into a pit filled with stones, and covering the same with a layer of soil every day. This pit must be kept covered.

6. *To prevent the spread of disease by the housefly:* "Since flies breed only in filth, the first thing to do is to render it impossible for the fly to reach any of the accumulations unavoidable around habitations. This is done: (1) By destroying filth wherever found. (2) By rendering it distasteful or poisonous to flies or their larvæ by the use of lime, kerosene, oil of pennyroyal or cresol. (3) By excluding light from the receptacle or by screens which the flies cannot pass. The most difficult part of an anti-fly campaign is teaching the people to dispose of their garbage properly. No amount of screening, trapping, or poisoning will make up for careless disposal of filth and waste. All such materials must be promptly destroyed or buried. If a really good suspension of milk of lime (calcium hydrate) is mixed with the garbage or refuse, the eggs and pupæ or maggots of the fly are at once destroyed, but it must be made to come in contact with the eggs or maggots to do any good. Kerosene oil is more effective, but more expensive. Where crude oil of low grade distillates are procurable, the expense is much lessened. Oil of pennyroyal, in the proportion of 1 ounce to 1 quart of kerosene, is very distasteful to the adult fly, as well as fatal to the young, and a small quantity sprinkled around the garbage can is sufficient to keep away all flies. The greatest drawback is the expense. Cresol is not expensive, and may be used freely in 2 per cent. emulsion. Privy vaults, manure bins, and similar places must be made and kept perfectly dark. Screens must be made automatically self-closing, otherwise they are sure to be left open and to fail of their object."—(Gardner and Simond's *Practical Sanitation.*) Fly poisons, flytraps and fly papers may also be used.

7. *To minimize the presence of diphtheria in a hospital for children:* The isolation of all cases and carriers; all who show cultures containing organisms which morphologically resemble the diphtheria bacillus should be isolated, whether the strains are virulent or not. Cultures should be taken from both nose and throat. Convalescents should not be released from quarantine until at least two cultures taken from both nose and throat are negative. All persons within the institution, both inmates and administrative force, should then be tested to the Schick reaction. Those reacting positively should be given a prophylactic dose of diphtheria antitoxin (1000 units). The immunizing dose may be repeated every ten days or two weeks as long as the danger persists. Those who react positively to the Schick test may be immunized with a toxin-antitoxin mixture. Each cubic centimeter of the mixture contains from 80 to 90 per cent. of the L+ dose of toxin, and one unit of antitoxin. One cubic centimeter of this mixture is injected subcutaneously and repeated three times at intervals of six or eight days. The results as determined by the Schick reaction produce an immunity in about 25 to 30 per cent. of injected individuals within four weeks; the remainder react slowly, in four months to two years. In addition to the above-mentioned measures care must be taken that the infection is not spread by the use of cups, spoons, dishes, toys, towels, handkerchiefs, and other articles used in common. The infected discharges should be rendered harmless at the bedside, and all objects that come in contact with the discharges from patients or carriers

should be disinfected. A general fumigation with formaldehyde may be practised, but in a well-ordered institution special cleanliness of floors, walls, and other surfaces will suffice.—(From Rosenau's *Preventive Medicine and Hygiene.*)

8. By the *mechanical filtration of water* is meant the *rapid* filtration of the water through sand, after a chemical precipitant (such as aluminium sulphate) has been added to the water. It is called *rapid* filtration in contradistinction to the *slow* filtration method or English method.

9. *Antityphoid inoculation* has been thoroughly tested, especially in the American army, and is of the greatest value. It is useful for those who have to live in infected localities, and for those who attend typhoid patients. By this means typhoid can be reduced to a minimum. Leishman reports: "In 5,473 soldiers vaccinated against the disease, 21 took it and 2 died; in 6,610 soldiers practically under the same conditions, who were not vaccinated, there were 187 cases and 26 deaths; that is, among the vaccinated soldiers there were 3.8 cases per thousand and among the unvaccinated 28.3 per thousand."

Method of immunizing against typhoid: The vaccine is administered subcutaneously over the insertion of the deltoid muscle; the site of the injection should have been previously painted with tincture of iodine; intramuscular injections are to be avoided; after the injection has been given the iodine is wiped off with a pledget of cotton and alcohol; no dressing is needed; the syringe and needle must be sterile; three such injections are given at intervals of about ten days; the dosage for adults (of 150 pounds weight) is 500,000,000 bacilli for the first injection, and 1,000,000,000 bacilli for the second and third injections; each of these amounts is contained in about 15 minims, or 1 c.c.; for a child weighing 50 pounds the dosage should be about one-third of the above, or a little more, for children take the injections very well.

10. "*Open-air schools* for children who are or are suspected to be tuberculous are becoming more and more common. In these, except in the worst of weathers, most of the teaching is given out-of-doors, and the timetable is so arranged as to allow of the pupils having certain periods of rest."—(Porter's *Hygiene and Public Health.*)

11. *Disposal of human excrement in a military camp:* "For permanent garrisons, sewerage systems with water carriage are possible and desirable. For temporary encampment, burial or burning are the most satisfactory methods. Various types of incinerators for this purpose have been designed, . . . but they are clumsy, heavy, and unless carefully tended prone to become nuisances. The best method is to burn the material with crude oil, which is simply poured into the pit and lighted. In firing, some straw or other light combustible stuff should first be thrown in."—(Rosenau's *Preventive Medicine and Hygiene.*)

12. *Principles to be observed in the construction of a modern hospital for contagious diseases:* "The site must be carefully chosen, must be of sufficient size, and readily supplied with water and easily drained. It should be isolated from neighboring buildings, but should not be more than 4 or 5 miles from the district it is to serve. The size of the site should be sufficient to provide a space of 1 acre for every twenty to thirty patients. No part of the building in which patients are to be accommodated should be nearer to the boundary wall than 40 feet. The wards are most conveniently constructed in blocks of two, one for male and the other for female patients suffering from one specific disease. In some places all the wards are on one floor, but if a large number of beds are required, in order to economize space, the blocks may be two stories high; but in any case they should be separated by a space of at least 40 feet. Preferably the wards should be rectangular in shape, and should not contain more than twelve or fourteen beds, allowing 150 or 200 square feet of floor space and at least 12 feet of wall space per bed, and 2,000 cubic feet of air space per patient. There should be windows on both sides, the total glass area providing at least 1 square foot to every 70 cubic feet of ward space. In height the wards should be from 12 to 15 feet. The walls should be smooth and impervious, so that they may be easily washed down. Since windows are numerous, ventilation should be easily carried out, but additional air inlets and outlets may be provided. . . . For artificial lighting electricity is best and most convenient. Water closet, bath and lavatory accommodations should be provided in connection with each ward, but should be entered through a lobby with a window to the open air, and not directly from the wards. In each ward block there should be a room for the use of nurses from which a view of the wards can be obtained. This is usually spoken of as the duty room. Occasionally a suite of three rooms is placed near the entrance to the block, all communicating one with the other, and used in connection with the discharge of patients. Of these rooms, one is that in which a patient about to be discharged leaves the clothing he has worn while in the ward, another contains a bath of water to which a certain amount of disinfectant is generally added, and the third a dressing-room in which he puts on fresh disinfected clothing preparatory to leaving the hospital. . . . Apart from the ward blocks, it is necessary to provide: an administration block; small wards for the isolation of doubtful cases; a laundry; a mortuary; a boiler house; a building to contain disinfecting apparatus; and so on. Of these, the administration block is the only one to which reference need be made. In it are placed the various offices in which the business of the hospital is transacted, as well as apartments for the medical and other officers. In the case of smaller hospitals it usually contains the sleeping quarters for the nurses and others, and commonly also the hospital kitchen. In larger hospitals a separate nurses' home is not uncommonly provided. The administration block need not be 40 feet from the boundary wall, but should be at least this distance from the ward blocks."—(Porter's *Hygiene and Public Health.*)

MOTILITY IN THE ANIMAL ORGANISM.

BY EGBERT H. P. WARD, M.D.

WHITE PLAINS, N. Y.

So far as I am aware, no definite and satisfactory theory has been proposed to account for motility in the animal organism. It has been considered to be in some way the result of oxidation of protoplasm with the attending liberation of heat and various waste products including CO_2 and certain nitrogenous compounds, but a clear conception of how this chemical process results in physical motion seems lacking. There has occurred to me, however, a possible explanation of this phenomenon of motility—an explanation which certainly has the merit of simplicity whether or not it may ultimately prove satisfactory.

In the first place, we seem to have associated the idea of *contraction* with motility, and this idea I believe has led us astray. Of course, contraction often apparently results from the action of motile mechanisms, but, not always; and when it does result, it is a secondary effect. The oxidation of the carbohydrate group in muscular action is often likened to an explosion; but our reason, dominated by the idea that contraction is the fundamental characteristic of animal motility—"contractility" being considered an essential characteristic of living matter—has recoiled from the impossible task of explaining how an explosion can result directly in contraction and, consequently, we have never applied to this phenomenon of motility the simple and well-understood physical principle according to which in mechanics explosive energy is readily converted into motion; which is, of course, the principle of *expansion*. Hence we have never regarded the CO_2 liberated in muscular action, for instance, as the actual source of the energy manifested, as we know it to be in the gas engine; but merely as a waste product to be eliminated as rapidly as possible, lest it accumulate in the muscle and cause "fatigue."

This, then, is fundamental to my hypothesis—that all forms of motility in animal organisms are essentially similar and all are due primarily to expansion caused by oxidation of the carbohydrate group in the protein molecule, resulting in the formation of CO_2 and H_2O with the liberation of heat—just as in the automobile cylinder; and, in addition, the explosion tears apart the protein molecule to a certain extent, splitting off one or more nitrogenous groups. The CO_2 then exercises its expansive force, which is transformed into motion useful to the organism by methods varying in the different types of motion; and is then eliminated as a waste product just as it is from the automobile cylinder. Only, of course, in the animal organism the explosion, the expansive force of the CO_2, and the elimination of the waste products—comparable in part to smoke resulting from imperfect oxidation—are all modified and slowed down by the fact that they occur in a liquid medium.

Now let us apply this principle to some of the types of motion in animals. We should naturally expect to find motility reduced to its simple terms in the most primitive type of animal organism—the common ameba; and I believe we shall not be disappointed in this expectation. An ameba is a single cell carrying on the struggle for existence on the simplest plane. It is just a globule of living matter with a layer of dense protoplasm which is in turn surrounded by a layer of less dense protoplasm. Just what the structure of this protoplasm is, we do not know. Under the microscope various structural details and currents of more or less dense fluid have been detected; and chemical analysis shows the presence of C, H, O, N, etc., atoms in great number, the largest chemical units to survive the analytical process being the protein molecule and the carbohydrates and fats. But whether the cell in life constitutes one huge organic molecule with an enormous number of atoms, the cell nucleus representing an extremely large and complicated organic nucleus in the chemical sense, with an immense number of side chains—protein, carbohydrate, fatty, etc.; or whether the cell is merely a morphological entity made up of many separate molecules dissolved or suspended in water and held together only by viscosity—we do not know. But we do know that during life the cell constantly gives off CO_2 and various nitrogenous compounds such as urea, together with heat; and that its life cannot be long maintained unless it is supplied with oxygen and with "food" in the shape of proteins, carbohydrates, etc. In other words, living protoplasm constantly undergoes a process of slow combustion and the oxygen used up is supposed to be combined with the carbohydrate group of the protein molecule; so that when the carbohydrate side-chain is split off and oxidized to CO_2 and H_2O, some group or groups of the protein molecule are broken loose in the process and eliminated wholly or in part as urea. Life, then, is essentially a process of the building up and breaking down by oxidation of these complex organic molecules; and every function of living matter, including motility, is probably the result of an intensification or a modification of this fundamental process. And if we are so impressed by the wonderful manifestations of life that we are inclined to doubt whether they can be

accounted for in this way, we need only consider the complexities of the simpler organic molecules, especially in the light of stereochemistry; and then consider the enormous number of atoms in the protein molecule and the likelihood that a number of protein molecules may combine together, as well as with the carbohydrate and fatty molecules; and lastly consider the possibilities in case the entire cell with its nucleus constitutes a single molecule! For example, some of the simpler organic compounds have the same molecular formula but differ from each other in certain respects, and we have been able to account for this difference only by assuming that the relations of the atoms in space differ as a righthand glove differs from a left. Might not bilateral symmetry in the animal organism be accounted for perhaps by assuming that the arrangement of atoms in the molecules of the cells, or at least of the nuclei, of the right and left sides of the body of the organism bears a similar relation? Of course I am not here attempting to explain the mystery of life, but simply drawing perhaps one step nearer to it. And one of its most remarkable characteristics is that the nearer we get to it the more mysterious and unfathomable it appears.

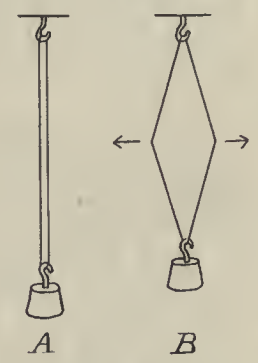
Let us, then, keeping these principles in mind, study the action of an ameba suspended in a drop of water of medium temperature. Even if the ameba is apparently motionless, we must assume that oxidation is taking place with the breaking down of the living protoplasm and the formation of CO_2, etc., and this oxidation is no doubt more rapid in the outer and less dense protoplasmic layer because here the combustible compounds are nearer the supply of oxygen in the surrounding water; and perhaps it is partly the CO_2 gas produced by the combustion and dissolved in this outer layer while gradually being diffused to the surrounding water, that causes the outer layer of protoplasm to be less dense. In the inner, denser layer of protoplasm perhaps the building-up process is proceeding more rapidly than the breaking down or oxidation, this process consisting partly in the synthesis of the carbohydrate molecule with some combination or modification of protein molecules and taking place probably under the influence of the nucleus. The entire ameba might be compared to a candle flame, with the wick in the center furnishing the fuel which in the dark area surrounding the wick is volatilized and partly broken up (or digested and assimilated) and in the light outer area is oxidized. Just so, perhaps, the proteins, carbohydrates, etc., taken in as food are split up and resynthesized in the dense inner layer of protoplasm by the action of the nucleus which may have the properties of, or may produce, one or more enzymes, and thus acts like the candle wick in furnishing the fuel.

Thus the life process goes on in the ameba, but the oxidation is comparatively slow while the organism is at rest, and the CO_2 produced diffuses into the surrounding water as rapidly as it is formed. But if a positive stimulus be applied to the ameba from a given direction—such as food substances dissolved or suspended in the water—oxidation will become more rapid in the protoplasm on the side stimulated, CO_2 will be formed faster than it can be diffused and will cause the protoplasm on that side to expand and bulge out in the form of a "pseudopod." If the stimulation keeps up this process will continue, the pseudopod will enlarge, and the rest of the ameba will be partly drawn into the advancing pseudopod by the action of viscosity, and partly will flow into it in currents of fuel drawn onward by the draught of combustion, like oil in a wick. On the other hand, if the stimulus is a negative one such as an advancing current of cooler water, the normal oxidation of the protoplasm on the side negatively stimulated will be reduced, less CO_2 will be formed on that side, and it will accordingly contract and the balance of tension being upset, the other side will expand and form a pseudopod and the ameba will flow away from the source of stimulation. For we must remember that oxidation with formation of CO_2 is constantly taking place, especially in the outer layer of protoplasm, and this produces a centrifugal expansive force tending to disrupt the protoplasmic sphere in all directions radiating from the center. But because the CO_2 can gradually diffuse through the protoplasm into the surrounding water and can partly occupy the interstices of the protoplasm, the pressure never becomes great enough to overcome the viscidity and disrupt the organism. And because the oxidation and therefore the resulting expansive force of the CO_2 would be equal in every direction, no one part of the surface would bulge out into a pseudopod. But if, due to a negative stimulus, the oxidation on one side be greatly reduced or suspended, the expansive force on that side would be lost and that side would shrink in allowing the other side to bulge out into a pseudopod. And, of course, once a pseudopod is formed, the tendency would be to enlarge it, as a greater surface is presented for oxidation; also, the negative stimulus, if it continued to act, would continue to reduce oxidation and hence pressure on the stimulated side, which would continue to shrink, allowing the other side to continue expanding and forming pseudopodia. Thus a negative stimulus would repel the ameba just as definitely as a positive one would attract it, both acting directly on the protoplasm; a stimulus that increases oxidation, that speeds up the vital processes, being a positive stimulus; while one that decreases oxidation and slows down the vital processes is negative. Thus I believe we can explain ameboid motion, which occurs not only in the common ameba and many related forms, but also in the white blood corpuscles in higher animals. This is the simplest type of animal motility because no special mechanism exists to confine or regulate the pressure resulting from the expanding CO_2, or to apply the force generated or change its direction.

The next higher type of motility is probably represented in the action of the *flagellum*, the locomotive organ of the flagellates. In these organisms the cell is similar to that of the ameba but surrounded by a cuticular membrane and at the anterior end, as a rule, there projects a thin, long whip-like protoplasmic process called a *flagellum*, also surrounded by a membrane. This is the motile organ and movement is confined to it excepting that the less dense outer layer of protoplasm of the cell body probably circulates through it. Now if a positive stimulus affects one side of the flagellum, it causes increased metabolism in the form of

oxidation along this side of the protoplasm just under the cuticle with resultant liberation of CO_2 which expands causing this side of the flagellum to stretch and get longer than the other side; and the flagellum accordingly makes a rapid sweeping movement toward the other side. Then the CO_2 partly escapes through the stretched membrane of the stimulated side and partly diffuses through the entire protoplasm of the flagellum equalizing the pressure, and the flagellum returns to its original shape. Meanwhile, the currents in the outer protoplasm of the cell carry away the residue of CO_2 and other waste products, and if the stimulation persists the process is repeated and the organism is headed toward the source of stimulation. Then the flagellum, having a slightly spiral movement, causes the cell to rotate around its long axis, passing through the flagellum, the flagellum rotating with it, and thus successive sides of the flagellum are subjected to the stimulus and a continuous series of lashing movements is set up which carries the organism toward the source of stimulation. It is interesting to note that in Mastigamœba we have an intermediate form between the ameba and the flagellates, a flagellum being present as well as ameboid movement by means of pseudopodia. The same general principle applies to the ciliates, in which the motile mechanism consists of a number of cilia which are like small flagella with a simple sweeping motion like oars. Probably increased oxidation with liberation of CO_2 and expansion along one side of the cilium causes it to sweep in the opposite direction and propel the organism. But there are so many cilia around the cell as a rule and the cell body itself in the ciliates is so complicated and shows such specialization that the problem of orientation is much more complex than in the ameba and the flagellates, and possibly the coordination of ciliary movement is controlled through the cell body and not directly by the action of the stimulus on the individual cilia. Some cilia may be stiffened in the center by axial rods and some observers have detected muscle fibrils and perhaps even nerve fibers in the cell body, and possibly some cilia are moved by muscle fibrils attached to the axial rods. But with both flagella and cilia the movement is much more rapid and violent than in the pseudopodia of ameba because the oxidation takes place along a more extended surface and the resulting explosion and expansion are more sudden, and the surrounding membrane produces a momentary compression of the CO_2. Furthermore, the flagellum and the cilium constitute a mechanism for changing the direction of the force generated—the expansion along one side of the flagellum or cilium in a direction parallel to its axis is changed into a movement of the cilium in a direction at right-angles to its axis, due to the membrane stretching on the expanding side and holding fast on the other. Compare this mechanism with the motor organ of plants, where the movements are due to an increase or a decrease of water pressure in the cells along one side of a flexible axial rod. These movements can be very rapid too, and the only difference is that the plant movement occurs in a gaseous medium (the atmosphere) and the differential pressure along the two sides is due to water, whereas in the cilium and flagellum the movement takes place in an aqueous medium and the differential pressure is due to a gas —CO_2. Compare also the warping of a beam or stick exposed to moisture on one side. We find ciliary action also in ciliated epithelium, where the cells are stationary and the cilia cause movement in the surrounding medium—*e.g.* in the respiratory passages of man where they carry up phlegm and foreign particles of dust, etc., to the throat. Here I believe the ciliary motion is dependent upon the same principle, whatever may be the influence regulating the direction and rhythm.

The last and most important type of animal motility is that occurring in connection with the muscle fiber, and it is also the most complicated in its specializations. Now, we have so closely associated the idea of *contraction* with muscular action that we have come to consider contraction as the fundamental process in all animal motility, and have even made the terms *motility* and *contractility* almost interchangeable in this sense. But even in muscular action, contraction is a more or less final result and is caused primarily by *expansion.* In fact, probably no actual contraction takes place in the size of the muscle excepting in one direction, and this is merely the result of an expansion in the opposite direction. The stimulated



muscle broadens and shortens but it does not really *contract* at all, and, as a matter of fact, probably actually increases in bulk. A simple illustration will suffice to show the fundamental principle of muscular action. Take a loop of string and hang one end on a hook and suspend a weight from the other end as in the accompanying illustration. Then pull apart the sides of the loop in the direction of the arrows as in Fig. B. The weight will be raised by the shortening of the loop.

If, instead of a loop of string, we take a long, narrow fusiform bag made of some material in the meshes of which the vertical fibers which carry the weight are inextensible while the horizontal fibers running around the bag are either elastic or so loosely woven as to be extensible; place a small quantity of an explosive mixture in the bag and ignite it; the bag will expand laterally, but, not being able to expand vertically on account of the inextensible vertical fibers in its walls, the horizontal fibers will be blown out so far that they will pull the vertical ones with them and shorten the bag and lift the weight. Then as the expanding gases slowly escape through the meshes, the bag will slowly collapse and extend again. This, I believe, is the essential principle of muscular action and a skeletal muscle is simply an extremely dense

network of fibers longitudinally inextensible which run continuously through the sarcolemma sheaths of the muscle cells and are gathered together at the ends into the tendons; with each sarcolemma sheath filled with a protoplasmic substance—the muscle fiber—so modified and so disposed as to be capable of rapid and continued oxidation resulting in the liberation of CO_2, which expands each sarcolemma sheath at right-angles to its long axis and correspondingly contracts it in the direction of its long axis owing to its inextensibility in this direction. And the transverse expansion and longitudinal contraction of the entire muscle is the sum of the transverse expansions and longitudinal contractions of all the sarcolemma sheaths. The expansion being the primary and fundamental manifestation of energy and the contraction a secondary mechanical effect. In other words, instead of one big bag widening and shortening we have in the muscle a lot of little bags widening and shortening. Then the CO_2 diffuses through the walls of the sarcolemma sheaths, to be carried away by the blood, allowing them to collapse again, and the muscle is said to relax. In involuntary muscle and cardiac muscle the sarcolemma is not so strongly developed, but there is a continuous sheet of fibrous membrane holding the muscle fibers in its meshes; and, in fact, the sarcolemma of voluntary muscle is simply a dense thickening of this membranous sheet around each fiber the better to confine the CO_2 and get more power out of it.

Let us now consider the evolution of the muscle fiber and try to apply this hypothesis to the varying structure and properties of the different types. Some observers have thought they could recognize primitive muscle fibrils even in some of the ciliates, as *Paramecium*, where they appear to run longitudinally through the cell beneath the cuticular membrane and are supposed to cause the entire cell to shorten. And in *Steutor* and in the stalk of *Vorticella* protoplasmic differentiations have been detected that resemble muscular fibrils. These fibrils seem to constitute the ultimate "contractile" elements of all cells which in part or wholly show muscular differentiation. They appear to be long threads of protoplasm, probably of an especially combustible nature, enclosed in a delicate membrane which is attached to the cell wall at either end. On stimulation rapid oxidation would occur liberating CO_2 which would expand the membrane transversely and shorten it longitudinally, thus drawing together the parts to which its ends are attached. Thus we have a mechanism which is an improvement on the flagellum and cilium, for the expanding CO_2 is enclosed on all sides and continues to exert its expansive force for a longer time. It cannot escape from the membrane immediately because the water and viscid protoplasm clog the pores. And the water and other contents of the membrane being practically incompressible, and its solvent power for CO_2 limited especially at the higher temperature resulting from the oxidation, the CO_2 can exert considerable force for an appreciable interval of time. Probably in the flagellum, cilium, and muscle fibril the protoplasm is of an especially combustible and explosive nature, perhaps because the oxygen is stored up in a more available form than in the slow moving ameba. But, generally speaking, more oxygen seems to be used up to form CO_2 in muscular contraction than exists in combination in the muscle protoplasm. The explosive protein molecule with the carbohydrate side-chain is not like the molecule of nitroglycerin, for instance, where there is more than enough oxygen to satisfy the avidity of the C atoms. In continued muscular action it would appear that some of the required oxygen must be furnished from outside the fibril. Therefore, we would have CO_2 and other waste products diffusing out of the fibril and O and perhaps new fuel substances diffusing in. It is well to get as clear an idea of the primitive fibril as we can, for it is the motile unit of all muscle cells. To follow the evolution of the muscle cell, then, we find in *Hydra* that many of the ectoderm cells are contractile, with a portion of the cell more clearly set apart to perform the "contractile" function than in any of the protozoa. Well defined muscle fibrils are found in the jelly-fishes, as *Aurelia*, and also cells partly modified into a *striated* contractile portion. In the worms we find plain muscle fiber well differentiated, and so on up to the vertebrates and man, where we find three types of muscle fiber—the smooth or involuntary, the voluntary, and the cardiac. Let us now take these up one by one and in the light of this hyphothesis try to explain and correlate the peculiar structure and action of each.

1. *Smooth Muscle.*—The individual cells or muscle fibers are the most primitive of the three types, being fusiform in shape and from 0.05 to 0.15 mm. long by 0.005 mm. in diameter, thus varying from ten to thirty times as long as they are wide. This elongation enables the muscle fiber to shorten to a greater extent on "contraction," as a simple calculation will show that the amount of shortening possible bears a fixed relation to the length and the greatest shortening theoretically possible—when the cell expands to form a sphere—is slightly less than one-third of the length of the fiber when fully relaxed. There is an elongated nucleus in the center of the cell and the protoplasm is almost entirely differentiated into primitive fibrils running the entire length of the cell, these primitive fibrils being essentially similar in structure and function to those occurring singly or in groups in the partly differentiated cells of certain protozoa and other lower organisms. These fibrils are surrounded by the remaining undifferentiated protoplasm of the cell, called sarcoplasm, which is probably more or less continuous from cell to cell through the interstices of the white fibrous membrane which passes as a delicate sheath around each cell and forms in fact a continuous sheet through the muscle substance, serving to transmit the force of the contractions and supporting the nerves and blood-vessels. Thus the essential distinction between the cell with one or a few fibrils and the muscle fiber with its protoplasm almost entirely differentiated into fibrils consists (*a*) in the fact that more power is generated by the increased number of fibrils; (*b*) that the cell being filled with fibrils must expand and shorten as a whole when they expand and shorten; (*c*) that the CO_2 after diffusing through the membranes surrounding the individual fibrils is accumulated in the cell as a whole and, confined for a time by the cell

membrane and fibrous sheath, continues to expand the cell and do work, thus giving double expansion and prolonging the contraction, and (*d*) there being many of these muscle fibers collected together in a band of smooth-muscle tissue, the action of the single cell is multiplied many times and the effect in the form of a contraction is cumulative, the traction being transmitted by the inextensible white fibrous tissue in the meshes of which the muscle cells are enclosed. Where a layer of smooth muscle surrounds a hollow space, as the intestine, in contracting both the widening and the shortening of the individual muscle fibers, and of the muscle layer as a whole, are effective in reducing the size of the cavity—the shortening by lessening the circumference and the thickening by reducing the diameter directly. This is especially the case in a location like the pyloric opening of the stomach and is of great importance in the contracted postpartum uterus where the thickening of the muscle obliterates the cavity and prevents hemorrhage. Furthermore, in all muscles voluntary, involuntary, and cardiac, this action promotes the circulation of blood and lymph by squeezing the fluids out of the tissues. In voluntary muscle, an important instance of this thickening being utilized directly occurs in the sphincter ani where the almost continuous contraction makes economy of effort essential; and this action is of great importance in the heart also. Now, while the smooth muscle fiber is at rest, no doubt slow spontaneous combustion is going on in the individual fibrils and this produces enough CO_2 to keep the fibrils and the entire cell on a slight tension and gives the muscle its *tone*, and also generates heat, which goes to maintain the body temperature of the organism. But the CO_2 probably diffuses as rapidly as formed and does not accumulate sufficiently to expand the fibrils and cause the muscle to contract unless the muscle is stimulated; in which case it is liberated so rapidly that it accumulates and brings about a contraction. Then, after the stimulation has ceased, it takes some time for the accumulated CO_2 to escape and allow the muscle to relax. Probably, also, where there are so many fibrils packed together in the cell, and so many muscle fibers collected in the muscle, the heat generated is much greater than in a single contracting fibril, and causes more rapid combustion as well as increasing the expansive force of the liberated CO_2 and lessening its solubility. After reaching the outer wall of the cell, the nerve impulse is probably conducted to the individual fibrils through the sarcoplasm; and also from cell to cell, the sarcoplasm being probably continuous. This would account for the conductivity of muscle, a contraction starting in one part passing in the form of a wave in all directions; probably the heat generated by a contracting part spreading also to surrounding parts and increasing the combustible property of the muscle substance.

2. *Voluntary Muscle.*—This is the most complicated motile mechanism found in the animal organism, but it is only a modification of smooth muscle. The voluntary muscle fiber is much larger than the smooth fiber, being in some cases as much as 12 cm. in length and varying from 0.01 to 0.1 mm. in diameter. Thus it may be over 1,200 times as long as it is broad and accordingly has greater possibilities of expanding and shortening, being practically like the loop of string in the illustration mentioned above. This greater size is due to the fact that the voluntary fiber represents a number of muscle cells fused together into a syncytium with their nuclei lying along the outer wall of the cell, which is a very convenient location for them if their function is to select food substances from the blood and synthesize them into the general protoplasm of the cell and the highly oxidizable contents of the fibrils. The latter do not as a rule lie separate in the cell protoplasm or sarcoplasm as they probably do in the smooth muscle fiber, but are gathered together in bundles running the entire length of the muscle fiber and the sarcoplasm fills the spaces between the bundles and around the outer portion of the cell, possibly each bundle of fibrils in the voluntary muscle fiber being homologous with a single smooth muscle fiber. In the voluntary muscle fiber the white connective-tissue forming the sheath of the cell is much more dense than in smooth muscle and the thickened sheath is called the *sarcolemma;* but the inextensible white fibers running longitudinally in the sarcolemma sheaths are probably continuous from sheath to sheath throughout the length of the muscle and are attached to the bone at the origin of the muscle and collected into the tendon at the insertion; and thus the power of contraction is transmitted through them, not only in their tendinous portions but throughout the belly of the muscle as well. The fibers running around the sarcolemma in the other direction must be either elastic or so loosely woven as to be extensible, perhaps running in a diagonal direction, thus allowing the sheath to be distended transversely but not longitudinally. Now the individual fibrils in voluntary muscle are not homogeneous in their structure as is the smooth muscle fiber, but show alternate bands of light and dark substance and thus present a striped or *striated* appearance; and since the fibrils all lie parallel to one another in the bundles, and the light and dark bands lie at the same levels in all the fibrils, this striped appearance is imparted to the muscle fiber as a whole and hence the name of *striated muscle.* Furthermore, each light colored band is crossed transversely in the center by a delicate dark line—the membrane of Krause—and according to some observers there is also a light line across the middle of the dark band, known as Hensen's line; but whether this latter also represents a membrane or is an artifact is uncertain. We do not know enough about the contents of these light and dark bands to enable us to comprehend their significance directly, but a comparison of the functional characteristics of striped and unstriped muscle may perhaps give us a clue as to their meaning. Perhaps the most distinctive property of striped muscle is its ability to *contract* and *relax* rapidly. Now the rapid contraction might be accounted for in a number of ways, but the power of rapid relaxation may possibly, I think, be due to the structure which gives it its striped appearance. As we saw in the case of the primitive fibril in lower forms and in smooth muscle also, the contents of the fibril is there homogeneous; this means that the large protoplasmic molecules, partly per-

haps undifferentiated, and partly in the specially combustible form of fuel, are distributed evenly throughout the watery contents of the fibril and must seriously impede the escape of the molecules of CO_2 through the pores of the fibrillar membrane. Now, if we assume the lines of Krause and Hensen to indicate the presence of delicate elastic membranes stretched like partitions across the fibril, dividing it into compartments; and each compartment to contain a layer of dense, concentrated fuel forming the dark portion with a layer next to it of thin, watery plotoplasm; then the CO_2 liberated by oxidation of the combustible fuel could escape through the fibrillar membrane in the light area without having the large fuel molecules clogging up the pores and impeding it; and the partitions would keep the contents of the compartments from getting all churned up together when the fibril widens and shortens on contraction, etc. If this were the case, it might account for the discrepancies of observations regarding Hensen's line; for if the fuel were packed densely in the dark area, it would obscure the membrane whereas if the muscle were fatigued and the fuel supply attenuated the membrane would be more distinct. This arrangement would also facilitate the escape of other waste products from the fibril as well as the entrance of oxygen and new fuel supplies, and might be of great importance in the escape of CO_2 and the interchange of food and waste products from the inner fibrils in a dense fibrillar bundle where perhaps substances passing to or from the interior fibrils might have to pass through all the successive layers of fibrils surrounding them. This might be especially the case with the CO_2 liberated during a contraction, for the distended fibrils in the bundle would probably obliterate any space that might exist between them at rest, and the CO_2 from the inside fibrils could escape only by diffusing through the fibrils of each successive outer layer, and would thus exert *multiple expansion.* With these light bands in the fibrils all on the same level across the fibrillar bundle, and containing only a thin, watery solution, a path of escape would be presented right across the bundle. This at least suggests a possible interpretation of the light and dark bands of striped muscle. There are other less marked characteristics of voluntary muscle which can perhaps be explained by the stimulating mechanism, the arrangement of the fibrils in bundles, and the dense sarcolemma sheath; possibly, also, the combustible molecules may be more explosive. Now let us consider the *properties* of voluntary muscle. In the first place, it has a constant *tone* due not alone, as perhaps in smooth muscle, to spontaneous oxidation but also to constant slight innervation caused probably as a reflex from sensory impressions from the semicircular canals and elsewhere. But after the death of the organism the spontaneous oxidation in the muscles probably causes the contractions of *rigor mortis,* as there is no circulation to remove the CO_2 and it gradually accumulates until the heat generated has completed the oxidation of all the more unstable combustible material, after which the CO_2 gradually leaks out and the muscles relax. Now the nerve stimulus acting on the voluntary muscle fiber is probably more powerful than in the case of smooth muscle, since after the axis-cylinder of the nerve has penetrated the sarcolemma it ends in a special organ called the *end-plate* which may act like a cap to set off the explosion, which is probably conducted through the sarcoplasm to the fibrils. This is perhaps why the contraction is so rapid in voluntary muscle as compared with involuntary or smooth muscle, the former being like an instantaneous explosion set off by a cap, the latter like a slow explosion set off by a fuse—a single contraction in voluntary muscle lasting less than 1/10 sec. Now if stimulation is repeated at moderate intervals, each succeeding contraction up to about the tenth is more extensive than the preceding, constituting the phenomenon of "staircase contraction." This peculiarity of striped muscle might perhaps be explained by assuming that the first stimulus reaches only the fibrils in the outermost layer of the fibrillar bundles with sufficient force to cause a contraction; then after the outside fibrils have contracted and raised the temperature of the next inside layer, its fibrils become more susceptible to stimulation on account of the heat increasing the instability of the explosive molecules so that the next stimulus is able to explode them; and so on with each successive layer of fibrils and each successive stimulus until all the fibrils are expanding on each stimulation and the muscle reaches its maximum contraction. And, reversely, as the supply of combustible fuel becomes exhausted those fibrils in the middle of the bundles cease to contract first under the power of the stimulus which diminishes as it penetrates the bundle, and so on until even those fibrils on the outside of the bundles and subject to the full force of the stimulus fail to react. Thus after reaching a maximum height of contraction from repeated stimulation, the extent of the contractions gradually diminishes until the muscle ceases to respond to stimulation; this exhaustion probably being due more to lack of oxygen than to lack of fuel. Now after contraction has been repeated at short intervals, the muscle ceases to relax fully, due no doubt to the CO_2 being unable to escape at once from the inner fibrils in the bundles, and exerting its effect of multiple expansion as noted above. And if the stimuli are repeated at short intervals the CO_2 is produced so much more rapidly than it can escape that the muscle goes into a summated or *tetanic* contraction; following which, even after cessation of the stimulus, the muscle continues in a state of contraction, called *physiological contracture,* for some time; perhaps the heat generated by so many rapidly succeeding explosions causes combustion with liberation of CO_2 to continue for some time after stimulation has ceased, or perhaps the great pressure exerted by the CO_2, especially at the high temperature, may compress the alternate layers of white fibers in the sarcolemma and tend to close the interstices, thus making it difficult for the gas to escape until it cools off and the pressure is relieved.

3. *Cardiac Muscle.*—The third variety of muscle is that occurring in the heart, and it is intermediate in structure and function between smooth muscle and voluntary muscle, but differs in important respects from both. The cells are short and rectangular in shape, with square ends which often branch, and are enclosed and bound together by a continuous sheet of white fibrous tissue. The

nucleus is single (and hence we may conclude that the cardiac muscle fiber represents a single cell) and the protoplasm is partly differentiated into fibrils running the length of the cell parallel to one another; but arranged not in round bundles but in narrow rows radiating, as seen on cross-section, from the center of the cell, and with the undifferentiated sarcoplasm surrounding the nucleus in the center and extending in wide spaces between the rows of fibrils to the periphery of the cell and probably continuous from cell to cell. Thus easy passage through the cell is afforded for food substances passing to the central nucleus to be synthesized into sarcoplasm and fuel; easy access to the individual fibrils for storing fuel and oxygen in them, for the propagation of the contraction stimulus to all of the fibrils simultaneously, and lastly for the escape of CO_2 gas and other waste products from the fibrils and the center of the cell. This arrangement is more marked in the muscle of the auricles than in that of the ventricles, where the fibrils are more closely packed and the sarcoplasm less abundant accordingly; and this causes the striated appearance of the ventricular muscle to be more distinct, for the fibrils of cardiac muscle are also striated as in voluntary muscle. Furthermore, the fibrils are attached at their ends to the fibrous tissue enclosing the cell or perhaps to the ends of the fibrils in the adjacent cells, and thus perhaps the heart muscle might be considered to consist of a dense network of fibrils more or less continuous and bathed in continuous sarcoplasm. And when the fibrils widen and shorten on contraction, the traction would be transmitted directly through the fibrils themselves and not through them to the fibrous sheaths of the entire muscle cells as in smooth and voluntary muscle. And thus we see why perhaps the cells of cardiac muscle do not need to be long and narrow so they can widen and shorten extensively, the CO_2 after escaping through the fibrillar membranes into the body of the cell causing merely a swelling of the cell and not much shortening. Probably the expansion of the CO_2 liberated in all the fibrils during a contraction and exerting a secondary expansive effect on the cell membranes, before escaping into the blood, acts directly in expelling the blood from the chambers of the heart and especially from the ventricles; the shortening or contraction of the network of fibrils in the muscle serving principally to hold the ring and confine the pressure due to the swelling of the whole muscle. The ventricular muscle in systole does not appear to contract or shrink in size at all but actually to swell up and get larger with the exception of the apex, which is drawn up a little; and probably this is just what happens. The shortening of the individual fibrils causes a shortening or contraction of the entire network of fibrils ramifying through the muscle. This acts to some extent to diminish the circumference of the cavities of the heart; but principally it serves to form a rigid frame to support and confine the swelling of the muscle as a whole due to the expanding CO_2 liberated in the fibrils and passing from them to expand the entire cells within their restraining membranes; and this expansion or swelling causes the heart muscle, held in by the contracting network of fibrils, to bulge into the ventricular cavities and obliterate them, thereby expelling the blood. And that part of the swelling that cannot be confined by the contracting network becomes manifest externally as the swelling of the "contracting" ventricles. Thus, with the exception of motion of the ameboid type, the heart is probably the only motile organ in the animal kingdom in which the primary expansive force of the liberated energy of living matter is utilized directly as the principal source of power; but in the heart this primary expansive force is confined and its action regulated and directed by the secondary contraction force into which it is partly transformed by the muscular mechanism, and which in ordinary muscular action is the only directly useful result. Certainly the heart is a wonderful mechanism for the conservation of energy, as indeed it needs to be. The heart muscle exhibits the properties of *tone* and *conductivity* as smooth muscle does, and probably for the same reason; but it contracts and relaxes more rapidly than smooth muscle, the former perhaps because the fibrils are all directly exposed to the stimulus (and possibly because the combustible compounds are more explosive); the latter due perhaps to the structure which gives it its striation. It also recuperates rapidly after a contraction, perhaps because the fibrils are so accessible for the interchange of food, oxygen, and waste products with the sarcoplasm. But all these properties of rapid contraction, relaxation, and recuperation are less marked in the ventricular muscle than in that of the auricles, probably because the fibrils are more densely packed and the sarcoplasm less abundant. Probably the ventricles play a losing game during the active waking hours of the organism and can store up fuel only during rest and sleep. This significance of the arrangement of the fibrils in heart muscle for rapid contraction, relaxation, and recuperation is borne out by their arrangement in the wing muscles of insects where such excessively rapid contraction and relaxation are required and where rapid recuperation also must be essential; for here the individual fibrils are entirely separate and each one is surrounded by sarcoplasm. Probably the arrangement of the fibrils accounts also for certain peculiar characteristics of heart muscle. (*a*) To a stimulus strong enough to set up a contraction at all, the heart muscle responds with all the contractility of which it is capable at the moment—probably all the fibrils receive the stimulus simultaneously and contract together, not successively as they perhaps do in voluntary muscle where they are arranged in bundles. Thus stimuli repeated at short intervals cannot cause repeated and increasing contractions as in the "staircase" contractions of voluntary muscle, nor are tetanic contractions normally possible, or the phenomenon of contracture since no mechanism exists such as fibrillar bundles or a dense sarcolemma to store up and confine the CO_2. (*b*) On the contrary, heart muscle exhibits a *refractory phase* in which normally it is inexcitable, this refractory phase beginning shortly before systole and continuing a short while after it. As regards that portion just before systole, the explanation may be that the contraction—that is, the process of oxidation and liberation of CO_2—has already begun but has not progressed far enough to be manifest, and as regards

that portion of the refractory phase immediately after systole, it is a natural and necessary consequence of the fact that in performing the systole the heart has just used up all its normally available explosive mixture and there are no fibrils left in reserve as may be the case in voluntary muscle, and an interval of rest is required to get rid of waste products and replenish the supply of oxygen. This refractory period can be so shortened by raising the temperature of the heart muscle to 40° C., or by irrigation with calcium or sodium salts, that a tetanic contraction can be caused by repeated stimuli; and this perhaps means that under the increased temperature, etc., the stored fuel in the fibrils is rendered more combustible and the expansive force of the CO_2 is increased, or the elimination of waste products is hastened and the recuperation power enhanced.

Perhaps the most interesting, and certainly one of the most important characteristics of heart muscle, is its property of making rhythmic contractions, not only when normally functioning in the organism but even when removed from the heart in small pieces. This power of rhythmic contraction was at first thought to be due to intrinsic musculomotor nerve centers which rhythmically stimulated the muscle and could be controlled in turn by the vagi and sympathetic nerves. Then it was decided that this property was not due to any outside stimulus but was myogenic—dependent on some stimulus formed in the muscle itself. According to one theory advanced, the combustible compounds stored as fuel in the muscle fibrils are of such an unstable nature that, after being built up to a certain point, they spontaneously break down again liberating the energy of contraction. But the heart muscle, in addition to making these rhythmic contractions, is also excitable by stimuli from outside sources provided the stimulus does not reach it just before, during, or just after a contraction. This shows that the elimination of CO_2 and other waste products and the recharging of the fibrils with a new supply of oxygen and perhaps fuel does not consume the entire interval between normal rhythmic contractions, but that following the recharging of the gun there is normally a period during which everything is ready and waiting for the command to fire. This consideration leads one to reject the hypothesis that the rhythmicity is due to unstable compounds breaking down as soon as built up. Now, in working out the gross anatomy of the heart, we have found the only key to its *structure* lay in the study of its comparative anatomy and development. Let us, then, apply this method to the study of its *function*, keeping ever in mind the two great limitations of comparative anatomy and embryology: (a) that perhaps no existing type of animal may retain a particular organ in its most typical and generalized ancestral form, without modifications in the direction of either degeneration or specialization; and (b) that in the embryological development of any animal, while ontogeny may be (and no doubt is, in its general character and significance) a recapitulation of phylogeny, yet it is not a complete recapitulation—the tendency is to slur over or skip entire stages in the development of organs so that the process of development in the individual may be shortened. So that in studying the structure and function of any organ, the story of its embryological development must be read in the light of comparative anatomy; and in interpreting both we must depend upon a delicate sense of judgment in order to determine, amid its varying phases of structure and function in the development of the animal and its mature characteristics in more primitive related types, what may have been its generalized ancestral form and function; and our conclusions at best can be only hypothetical. Now, in the light of embryology and comparative anatomy, we are perhaps justified in assuming that the blood-vascular system originated, not from an enclosed portion of the cœlom, but from hypoblastic tissue by the secretion of fluid (the blood) by certain cells of the intestine, with the pressure of this fluid forming spaces in the cells which communicated and became lined with these cells. Perhaps among existing types certain of the marine worms—the *Chætopods*—retain the vascular system in a form most nearly approaching the primitive generalized type which seems to consist of a dorsal vessel above the intestine and a ventral vessel below it, these vessels communicating with each other directly by means of cross branches and receiving nitritive fluid from the intestinal sinus which gives off branches to both, and also giving off fine capillary branches to the body walls, etc. Now, these main vessels and the branches connecting them are probably all contractile in the primitive form, the contraction being in the form of a peristaltic wave passing along them; but with the formation of more complicated branches and more numerous capillaries, the contractile power tends to become localized and concentrated in the dorsal vessel or "heart" in the form of a *rhythmical peristaltic wave*, and in some of the arthropods this dorsal vessel becomes locally modified to form a definite heart which contracts rhythmically. In these primitive types the vascular system nearly always communicates with the cavity of the cœlom, either through valves or capillaries opening into it or else the blood from the arteries and capillaries empties directly into it and is returned from it to the heart—thus constituting the prototype of the lymphatic system in higher forms. Now, when we follow the development of the vascular system into higher types, we find that the vertebral heart originates simply from a main artery which has become bent upon itself and the musculature locally thickened, with various modifications in the size, shape, and arrangement of the interior giving rise to the chambers of the heart with the valves, etc., just as the stomach or gizzard is a specialized portion of the alimentary tract. The development and structure of the heart are comparatively well understood, but its function is what we are interested in here. In the higher vertebrates, in the human being, the circulation of the blood depends directly upon the heart alone. There are many secondary influences—the elasticity of the aorta and larger arteries equalizes and sustains the pressure during diastole, the musculature of the arteries and veins regulates the pressure, the action of the skeletal and other muscles, respiratory movements, etc., etc., all secondarily assist the circulation; but the heart is the pump, the actual *vis-a-tergo* of the circulating

blood—in other words, there is no peristaltic wave passing forward along the arteries and back along the veins to help the heart. Just as the musculature of the vascular system is concentrated in the heart, so also is the peristaltic wave which, in the primitive types of animal, probably passes clear around the main system of vessels to return to its starting point. If we might be justified in regarding the typical circulatory system in its most primitive form as, digrammatically, a single continuous vessel with a peristaltic wave passing around it rhythmically, noncontractile capillaries also being given off from it, then the human heart would represent a specially modified portion of this vessel with the contractile force concentrated in it and the peristaltic rhythm retained in it, although lost for the most part in the remainder of the vessel.

Now let us consider this diagrammatic primitive type of circulation more closely. The primitive blood vessels, developed perhaps from the intestinal wall, show the same peristaltic type of contraction as the intestine. Primitively, perhaps, this peristaltic contraction, starting at a given point, is conveyed from muscle fibre to muscle fibre by the power of direct conductivity more or less characteristic of all muscle tissue and dependent probably on continuity of the sarcoplasm from cell to cell. Now in the intestine a wave of peristalsis, started by stimulation at the anterior end, passes to the posterior end and ceases; there is no more muscle tissue to contract and the intestinal wall is at rest until a new stimulus at the anterior end sets up a new wave of contraction. But in a continuous vessel, like the diagrammatic primitive blood vessel, a peristaltic wave once started would continue to propagate itself rythmically around the vessel indefinitely, until a lowering of temperature or the death of the animal caused it to slacken or cease. Its rhythm would depend on the rate of conductivity in the muscle (which might vary with temperature, nutrition, etc.) and the length of the vessel around which it would have to travel before repeating itself. Now this, I would venture to suggest, is perhaps what actually occurred in the primitive ancestor of the vertebrates—a type which may have persisted for countless ages; and after millions of years, perhaps this habit of making rhythmical peristaltic contractions would become so fixed and essential a property of the circulatory system that in spite of modifications of structure, and rate of rhythm, the fundamental characteristic of *rhythmicity* would survive even after the contractile mechanism had become more or less localized in one part of the vascular system and modified into the complicated mammalian heart. This hypothesis would explain why the rhythmic contractions do not occur simultaneously throughout the heart muscle, or even throughout the auricular muscle, as we might expect them to do if the rhythmicity were due simply to an instability in the combustible molecule; whereas, on the contrary, they occur in the form of a *peristaltic wave* starting in the auricle at or near its junction with the superior vena cava, and passing thence over the auricles and then over the ventricles to the arterial orifices. Furthermore, this peristaltic form of contraction is invariable in all periods of development and in all hearts, vertebrate and invertebrate. And its rhythmic frequency is perhaps the same as if the wave of contraction had to pass all around the circulatory system and return once more to its starting point at the auricle to stimulate a new wave; only the continuity of the musculature in the vascular system has been interrupted by modifications—it is almost interrupted between even the auricles and ventricles and in disease may become completely so—it is interrupted in the elastic, nonmuscular aorta; and in the arteries, arterioles, and veins peristaltic action has been modified or superseded by direct vasomotor control. Its delay in passing from the auricle to the ventricle may represent the interval that would be required in passing through the muscular tissue that has been replaced by the fibrous tissue of the auriculoventricular septum. In any case, the wave is transmitted through this fibrous septum by a bundle of muscle fibers which has its root in the right auricle, runs thence through the auriculoventricular septum and is distributed in branches and twigs to all parts of either ventricle, bringing every part of the ventricles into simultaneous contraction. The ventricles if left to themselves have a slower rhythm than the auricles, this modification being perhaps associated with the specialization of the ventricular musculature in the direction of hypertrophy, the individual muscle cells being thicker, containing more fibrils more densely packed, and less sarcoplasm than is the case in the auricle where the muscle is more embryonic in character. The contraction in the ventricular muscle lasts longer than in the auricle, and it takes longer to relax; as might be expected, according to my hypothesis, from the dense arrangement of the fibrils, for the CO_2 cannot escape so quickly, as well as being formed more abundantly, nor can the fuel be replaced so readily. Hence the ventricular muscle must be more dependent on the rest secured during sleep for the replacement of stored fuel than is that of the auricle. The auricle might be likened to the "stroke" oarsman of a racing crew who has a narrower oar so that he can keep relatively fresh and set a stroke that may be most exhausting for the rest of the crew. Thus the inherited rhythm of the heart is given in trust to the auricle to guard and maintain intact and transmit to the ventricle, which must specialize in the heavy work. Accordingly, when the heart is removed the rhythm persists longer in the auricles than in the ventricles, as well as being of greater frequency; and the venous end of the heart is least sensitive to injury, beats longest after death, and is the first to recover after arrest. Another instance of this retention of inherent characteristics in peristaltic movement is furnished by the intestine —an organ probably nearly related to the vascular system. The downward direction of the peristaltic waves of contraction in the intestinal wall must be an inherent characteristic of the mechanism in the intestinal wall that controls them, whether this mechanism be nervous or myogenic; for when a portion of the gut is excised, and then reunited at the severed ends to the intestine, but in a reversed position, the peristaltic waves pass in the same direction in the reversed portion as they did before excision, but this means that they now pass upward instead of downward in relation to the rest of the

gut. Thus the intestinal wall has inherited from countless ancestors the fixed habit of having peristaltic waves in a downward direction and is dependent on the contiguous parts of the gut or outside nervous control only to start them or regulate their force and duration; but not, under normal conditions, to regulate their direction. Compare also the rhythmical waves of ciliary movement in the epithelial cells lining the upper respiratory passages, the movement being in one direction only.

Furthermore, the auricle, in setting the pace for the beating heart, is perhaps the ultimate timekeeper for the entire organism. For I doubt not that the regular, rhythmical beating of the heart, with the rate practically constant for the individual in health (however it may vary for different individuals, or in disease) furnishes to the subconscious mind its fundamental inherent sense of Time as a background, from which the facts of experience that go to make up the *train of consciousness* stand out in the light of the attention; just as the time record on a revolving drum furnishes a basis of reference for the curves representing any action we may study in the laboratory. Without this definite background we might indeed be conscious of a *succession* in the presentation of events to consciousness, but this sense of succession would be either confused by a multiplicity of events or interrupted by the irregularity of their occurrence. There would be no fixed basis in time to which to refer them, for time can be measured only by a succession of phenomena recurring at regular intervals. Now this is just what the regular beating of the heart furnishes, and it matters not whether it furnishes it directly to the subconscious mind by visceral sensations or indirectly by the increased oxidation in the nerve cells following each fresh wave of arterial blood.

Thus perhaps we may solve the mystery of the subjective sense of time—a mystery which the Greek philosophers could scarcely apprehend; which Kant analyzes with wonderful clearness in his "Critique of Pure Reason," but for which he could find no basis in experience; which Berkeley considered merely an abstract concept formed from the succession of ideas in consciousness: which Wundt and Spencer left unsloved after speculating as to whether the sense of time is continuous or made up of discrete occurrences; and which a recent authority, writing in the Encyclopædia Britannica (XI Edition) sums up as follows: "On the whole, then, we may conclude that our concrete time experiences are due to the simultaneous representation of a series of definite presentations both accompanied and separated by more or fewer indefinite presentations more or less confused; that, further the definite presentations have certain marks or temporal signs due to the movements of attention; that the rate of these movements or accommodations is approximately constant; and that each movement itself is primarily experienced as an intensity." Thus the rhythmical beats of the heart would be brought to the mind as "movements of attention" whose rate would be "approximately constant"; and would act as "marks or temporal signs" constituting a scale of time for the measurement of the "definite presentations" which are "both accompanied and separated by more or fewer indefinite presentations more or less confused," just as the time record on a revolving drum in the laboratory furnishes marks or temporal signs with reference to a series of curves more or less distinct and interwoven; and if the rhythmic beat of the heart is brought to consciousness through the waves of increased oxidation following the fresh supply of arterial blood to the nerve cells, then "each movement itself would be primarily experienced as an intensity." Thus the heart beat would furnish the physical basis of the subjective sense of time which was so beautifully analyzed by Kant, though he could not comprehend it. He considered that Space and Time belong to things, not in themselves, but only as we know them; Space being the form of *outer* sense, Time the form of *inner* sense; and neither of these concepts being given by experience, but rather being *conditions* of experience *supplied by the mind* from its *inward resources.* Little did Kant suspect, as he sat in his study absorbed in thought with his gaze fixed on that distant steeple, that the *inward resources* that supplied his mind with the concept of Time as a condition of experience were perhaps the subconscious impressions of the beating of his own heart.

Of course, this sense of time furnished by the heart as a graduated background for the study of experiences in their time relations is blurred by the multiplicity of experiences that accumulate against it in the life of the individual, and becomes less obvious and distinct as our other time experiences multiply; just as we may disregard the graduated scale in the eyepiece of a microscope and judge the dimensions of objects directly, once our judgment is trained. But this time scale is always in the background of experience and registers even during sleep; not, however, during loss of consciousness, from which we recover without any sense of the lapse of time—as, indeed, may occur also in very deep sleep. And perhaps the irregularities of heart action in fevers and other diseased conditions may partly explain the mental confusion and anxiety which are such distressing symptoms and which may possibly result largely from a loss or disturbance of our sense of time. When our hearts beat rapidly, clock or calendar time seems to pass slowly by contrast; and vice versa. Thus when, over a short period, our hearts beat rapidly in anticipation, time seems to drag by constrast. But this influence is modified by the number or intensity of experiences brought to the field of consciousness; they tend to distract our attention from the chronometer within us and we do not realize the passage of subjective time. Perhaps the fact that calendar time seems to pass more quickly as we grow older may be due in part to the gradual lessening in frequency of the pulse —our clock is running down and the day is spent sooner than we thought.

Thus I have attempted to apply my hypothesis to some of the more important phenomena of motility in the animal organism, and have attempted to suggest possible explanations for these phenomena in the light of this hypothesis. But whether or not my application of the hypothesis shall stand the test of time, or even whether or not it prove correct in the light of our present knowledge, of this I feel convinced: the action of a voluntary

muscle, like the rectus muscle of the thigh, is due to a shortening of the muscle between its tendons of origin and insertion, resulting in a traction on these tendons; now this traction must be transmitted to the tendons from and through the belly of the muscle by either (1) the inextensible white fibrous tissue which ramifies through the belly of the muscle forming the walls of the sarcolemma sheaths and is collected together at the ends to form the tendons, or (2) by the protoplasmic contents of the fibrous sarcolemma sheaths of the individual muscle cells; there is nothing else to transmit the traction. Now, when we consider the friable or liquid character of the protoplasmic muscle substance, how can we conceive of its transmitting any tractile force or even possessing any tensile strength, either taken as a whole and acting on the medial ends of the tendons, or as individual cells acting from inside on the ends of the many sarcolemma sheaths? To my mind, it is inconceivable and absurd. Very well, then, the traction must be transmitted from the belly of the muscle to the tendons by the inextensible white fibres spreading out from the tendon at one end and ramifying through the belly of the muscle and concentrated around the individual muscle cells in the sarcolemma sheaths, and finally gathered together to form the tendon at the other end. But how, then, can such a network of inelastic fibres be made to shorten up and exert traction? They are not elastic and cannot be made to shorten of themselves. The only way I can conceive of is by a force expanding them transversely and thus causing them to shorten longitudinally, just as we might stretch a piece of cheese cloth one way and see it draw up the other way. Now this force must be exerted from within the fibers, coming as it must from the substance of the muscle cells; and what sort of force must it be? Could a *contraction* of the protoplasmic contents of the network cause the network to be stretched out transversely and shorten longitudinally? Not that I can conceive of. Then it must be an *expansion* of the protoplasmic contents. Now how might this expansion be brought about? Well, we know that oxidation takes place in the protoplasm and a good deal of CO_2 is liberated and that this sort of chemical change is capable of liberating considerable energy in the cylinder of an automobile or the chamber of a twenty-inch gun; so why might it not be sufficient to cause a little expansion in a muscle fiber? Of course, in the present state of our knowledge, we may not be able to say positively that it is the cause of muscular contraction; but it seems as if it might be a sufficient cause and, so long as we know of no other, we might at least give it a little credit and not consider the Co_2 as merely a *waste product* or a possible "slight stimulant to muscular contraction" so long as there is not too much of it present, which seem to be the prevailing views with regard to it. If this be the nature of the force causing muscular action it would explain the *elastic* character of the traction exerted by a muscle contracting against resistance, an elasticity that suggests that of an expansive gas enclosed in a slightly extensible bag. This also would explain the "feel" of a contracted muscle. like the biceps for example, the compressibility and elasticity varying from flabbiness in the untrained muscle to the almost incompressible tension of the muscles of an athlete—just a question of the amount of Co_2 liberated and the rapidity of its liberation, and the strength of the sarcolemma sheaths to compress it. Furthermore, we can understand why muscles can really exert so little force and why the tendons have to be inserted so close to the joints in order to get the utmost range of movement possible even at the sacrifice of power. For theoretical considerations show that the belly of a muscle can shorten much less than one-third of its length.

Thus in higher forms the motile tissues are not directly exposed to the influence of positive and negative stimuli as is the protoplasm of the ameba, but are connected with the external world by delicate threads of combustible tissue—the axis cylinder processes of the nerve cells—which carry the stimuli to them, with modifications, in the higher forms, of the nature of reflex arcs and association centers, and specialized end organs to receive the various forms of stimuli. Now, if the contraction of muscle is really due to an explosive liberation of Co_2 in an aqueous solution of protoplasm, etc., may not the nerve impulse that sets off this explosion be comparable to the action of a long delicate train of powder in a fuse which carries the spark to the mass of powder to be exploded; and the motor end-plate to a cap at the end of the fuse to flare up and set off the explosion more quickly? Thus the nerve impulse would be essentially similar in nature to the muscular contraction, except that it is much slighter in extent and perhaps the combustion more explosive in character, being conducted at the rate of 100 feet per second in the axiscylinder process and about ten feet per second in muscle. Either in nerve or in muscle the explosion can be started at any point by an electrical or other stimulus, but normally the muscle receives it from the nerve, which in turn receives it from the external world either directly or modified by the action of the reflex arc or the higher association centers in the light of experience inherited or acquired; inherited experience constituting *instinct*, and all experience having its physical basis in paths blazed through the complicated nervous network by previous impulses. The fact that the Co_2 and heat produced by prolonged stimulation of a nerve are scarcely if at all measurable is not of any significance to the contrary, nor the fact that the expenditure of nervous energy in mental work or otherwise produces no measurable increase in waste products eliminated—this is to be expected. The actual amount of combustion in the nerve tissue would be small because it would not need to be otherwise—nerve impulses do not accomplish anything until they become manifest in muscular contractions; just as a fuse, if long enough, might keep on burning indefinitely—it would not make any smoke to speak of or produce any results until it finally reached the powder and exploded it, and then the smoke from the fuse would be lost in that of the powder. Just so, nerve impulses may originate from stimuli acting on sensory organs and travel to the nuclei of origin of the sensory nerves and then chase themselves around the higher brain centers indefinitely—they are like a spark running around an

immensely complicated network of delicate fuse with the continuity of powder in it interrupted in places; the fuse may sputter and the sparks fly, but the combustion is almost *nil*, there is no smoke, no noise, no work done until the charge of powder is finally reached and exploded. And the debilitating effects of too much nervous strain are probably due as much to the absence of sufficient muscular action as to the presence of too much thought, although a nerve impulse once set up by an external stimulus must probably find somewhere an outlet in the form of muscular or other action. And it may be that after a train of thought has passed around the exceedingly complex network of the central nervous system, like a spark wandering around a complex network of fuse, and has at last found the proper outlet to action—like a bewildered wanderer in the mazes of the Labyrinth of Crete who, exhausted, has finally found his way out—its force is so attenuated that it requires an additional impetus from the cerebellum to strengthen it into a nerve impulse capable of contracting many muscles and producing results; the cerebellum is supposed to have some such action, or at any rate does not seem to have any other. But a nerve impulse traveling around a simple reflex arc would no doubt retain sufficient force to stimulate a reaction.

North Street and Ward's Lane.

THE SURGICAL DISORDERS OF DIGESTION.*

By W. D. HAINES, M.D.,

CINCINNATI, OHIO.

FELLOW OF THE AMERICAN COLLEGE OF SURGEONS, ASSOCIATE PROFESSOR OF CLINICAL SURGERY, MEDICAL COLLEGE, UNIVERSITY OF CINCINNATI; ATTENDING SURGEON TO THE FIRST SURGICAL SERVICE, CINCINNATI GENERAL HOSPITAL.

THE disorders of digestion go to make up the greater number of complaints concerning which the physician is consulted. In listening to the story of a patient who is complaining of dyspepsia we are prone to center our thoughts upon some disorder of the stomach itself, and in consequence become confused in our conclusions relative to the patient's actual physical condition. The case records of surgeons will show that extragastric lesions have been found as causative factors in the production of the symptoms in 90 per cent. of the dyspeptics who come to operation for relief.

In examining a patient for "stomach disorder" it is a very good rule to follow the advice of the automobile mechanic to look at everything else before you examine the carburetor. If you can accept the above as correctly representing actual conditions founded on a liberal experience in dealing with living patients, the writer will ask you to visualize a human being without a stomach while considering with him some of the most frequent pathological lesions concerned in the production of dyspepsia, indigestion, faulty metabolism, and allied physical conditions provocative of so much discomfort, pain, and danger in those who confide their welfare to our keeping.

Of all causes operative in the production of digestive disorders, chronic appendicitis is by far the most frequent. In discussing chronic appendicitis one must for the nonce divorce his thoughts from the acute manifestations of the disease, and learn to differentiate between the relapsing and chronic processes in appendicitis.

The relapsing form of the disease will present in from 50 to 75 per cent. of the patients who have had a frank, outspoken, acute attack, and the patient himself will materially assist with his story in putting you on the right road to success in interpreting the symptoms. In the chronic form of the disease, however, the symptoms are usually vague, and the history as related by the patient rarely indeed contains much of value to the examiner, aside from the one suggestion by the patient that he has stomach trouble; nevertheless, the correct interpretation of a well written clinical history as given by the patient is our chief guide to the diagnosis of chronic appendicitis.

If the history does not point to a diseased appendix as a cause for the symptoms, it may serve a useful purpose in the scheme of differentiation by exclusion, that is to say, the history may not show what organ is diseased, but it may indicate what organs are not diseased. Perhaps I may not do better in presenting this phase of the subject than to report briefly a case of chronic appendicitis.

A young man who consulted the writer some years since said that he had been losing weight, strength, and ability to work or think connectedly. He felt badly at all times, and was not refreshed after a night's sleep. His sleep was usually broken by troublesome dreams. He had a bad taste in his mouth, and although he ate at regular intervals about the usual amount of food, it was more a subject of habit than his appetite which caused him to join the family at table. The presence of food in his stomach seemed to have little influence on his general condition, although he complained of some distress in the abdomen which was present at all times during the waking hours. His urine was scanty, high colored, and left a burning sensation in the urethra after passing. The patient never had a bowel movement except after taking a cathartic. He was a man of exemplary habits and had a splendid family history. The chief concern of this young man was that he was losing his mind. He became very morose at times, and while in this mood would say to his companions that the world would be better off without him.

His temperature, pulse rate, and breathing were normal. The heart and lung sounds of the patient revealed nothing at variance with health. His tongue was swollen, carried the imprint of the teeth in its margins, and was heavily coated. The legs, arms, head, and neck were normal save for a marked flabbiness of the muscles. The abdomen was prominent, but the musculature of its walls gave way readily to pressure of the hand of the examiner.

Moderately firm pressure elicited pain in all parts of the abdomen when it was applied. No one place seemed more sensitive than another below the level of the umbilicus. The anal sphincter was firmly contracted and the introduction of the gloved finger increased the abdominal pain, induced a sensation of nausea, and caused the patient to complain bitterly of this part of the examination.

A tentative diagnosis of chronic appendicitis and advice to have the appendix removed were accepted by the patient. At operation a chronically inflamed, white appendix with indurated walls and partially obstructed lumen was removed. Great relief followed during the patient's stay in the hospital, and complete recovery from all symptoms in the course of three or four months after the operation. The patient has had no return of his symptoms, although several years have elapsed since the above experience was recorded.

This illustration is cited only as a concrete ex-

*Read before the Ohio Valley Medical Association, Evansville, Ind., November 11 and 12, 1919.

ample, and must not be regarded as typical of the disease which we are discussing. In a general way we may say that patients having chronic appendicitis will show nerve irritability and stomach disorder.

The general well being of the patient is seriously deranged, but he is unable to describe definitely or to locate his trouble. Rarely, indeed, do these patients give a distinct history of having had an acute attack of the disease, and this materially adds to the confusion in the mind of the examiner, who is accustomed to thinking of appendicitis only in surgical terms.

The age incidence of the disease is interesting, as the following analysis of 2368 cases by Klotz, published in "General Surgery" for 1919, will show: Two per cent. of the number occurred in the first decade of life, 15 per cent. in the second, 38 per cent. in the third, 28 per cent. in the fourth, 11 per cent. in the fifth, 2 per cent. in the sixth, and 1 per cent. for the remainder.

Dyspepsia, constipation, or irregularity of the bowel, and impaired health are very constant concomitants of chronic appendicitis. The patients complain of more or less discomfort in the entire lower abdomen, which is usually persistent in character, and increased on rectal examination, but they seldom use the word *pain* in describing their symptoms.

Deposition of the inflammatory products which accompanies this disease diminishes the caliber of the lumen of the appendix, and the resultant contraction of scar tissue ends in obliteration of some part of the lumen in a certain percentage of the cases, thus preventing the entrance of barium in the *x*-ray examination.

In seeking for an explanation of the mechanism in the production of stomach symptoms in these cases, one has but to recall that the base of the appendix is freely supplied with the anodal tissue of Kieth, and draw his simile from a similar pathological phenomenon which occurs higher in the gastrointestinal tract, viz., pylorospasm.

May we not reasonably conclude from this very incomplete presentation of the subject that it becomes an imperative duty on the part of the physician in examining a patient to exclude chronic appendicitis before seeking for other causative factors in the production of disordered digestion?

Subacute and chronic cholecystitis are second in frequency only to the foregoing in the production of digestive disorders; indeed, some observers of broad experience maintain that gallbladder and duct disease outweigh chronic appendicitis in the rôle of causative factors. Unlike the preceding condition, the differential diagnosis is more readily made, owing to the presence on the history sheet of a description of a well marked attack of the acute manifestations of cholecystitis.

In chronic infectious processes of the gallbladder and ducts one of the most important of the several secretions essential to normal digestion is seriously impaired, and in consequence thereof symptoms follow which are numerous and far-reaching.

Perhaps one of the best illustrations of the difference in the behavior of infective germ life as modified by anatomical conditions is presented in this field. If the disease process is limited to the hepatic or common ducts the symptoms will be transitory, and relief will follow free purgation, owing to the readiness with which natural drainage follows removal of the edema in the mucosa lining the duct; but when the cystic duct and gallbladder are invaded the scene rapidly changes from the mild manifestations of duct involvement to the flamboyant symptoms of acute cholecystitis.

The invading organism may be identical in each instance, the tissues may be isoanatomic, and still there is a wide descrepancy in the subsequent histories. The duct case recovers quickly, but the infected cystic duct and gallbladder, owing to their peculiar construction, are soon obstructed by the swollen mucous membrane, which in turn favors stasis, chronic inflammatory changes in the walls of the cystic duct, and stone formation. The gallbladder and its duct in the presence of acute infection lend themselves admirably to the scheme of the chronic process which so frequently supervenes in the absence of timely surgical intervention.

In addition to edema and stone there is present in many of the patients a third factor in the mechanics of gallbladder and duct obstruction, viz., adhesions.

Whether adhesions are due to the variety of infection or something inherent in the individual makeup of the patient has not been fully determined, but their presence in the region of the gastrohepatic omentum, duodenum, and hepatic flexure of the colon serve to impede the flow of bile, and induce symptoms which will find expression in digestive disturbances.

Firm adhesions between the bile ducts or gallbladder and the duodenum may so distort the latter as to interfere with the passage of the stomach contents, and this leads to the subject of the intimate interrelationship of the digestive group. The profession has recognized for a long time the frequency with which disease of the bile passages was associated with hyperacidity of the stomach, but has left undetermined the salient point as to whether hyperacidity was a cause or an effect.

Pawlow in his experiments showed conclusively that pylorospasm may be produced by the passage of highly acid stomach secretions over the mucosa of the duodenum.

If the irritating influence of an excess of acid will induce food retention in the stomach it is only fair to suppose that bile stasis will follow when the mucous lining of the duct bearing a portion of the duodenum is subjected to the same irritating influence, thus favoring stagnation of bile and the invasion of germ life.

The past history of patients suffering from gallbladder disease will usually contain a description of one or numerous attacks of acute cholecystitis, with a long array of symptoms intervening between the attacks. The latter will include distress after eating, occasional sharp pains in the upper abdomen, bad taste in the mouth, furred swollen tongue, lumbago, lack of vigor, vertigo, and blurred vision.

In consequence of an altered metabolism, the skin of these patients becomes dry, and desquamation takes place rapidly. This gives rise to an annoying itching which is a very significant sign in the presence of other gallbladder symptoms.

Although the appetite is greatly impaired in most of the diseased gallbladder subjects, still there is a marked tendency in many of them to take on the "middle age spread." Fats are generally excluded from the diet and eructations, nausea, pain and vomiting occasionally follow the taking of food into the stomach. The sclera and skin are usually discolored, the patient is constipated and the stools are light in color.

In examining the abdomen of a patient suspected to be the subject of gallbladder disease, the supine position, with the thighs fully flexed, will materially assist the examiner. Another very good position is obtained by having the patient sit erect on the examining table with his thighs at right angles to the body. The examiner, sitting on the table behind the patient, passes the examining hand to the region of the gallbladder and makes firm pressure over the region with the tips of the fingers at the end of a deep inspiratory effort on the part of the patient. The protective spasticity of the abdominal muscles over the gallbladder area must be differentiated from that caused by duodenal ulcer, renal colic, and pylorospasm.

Surgical literature formerly contained many chapters on the subject of chronic pancreatitis and its importance as a causative factor in the disorders of digestion, but Robson, who did so much pioneer work in conjunction with Mr. Cammidge on disease of the pancreas, does not refer to its influence in this connection in his chapter on chronic pancreatitis, written for the 1913 edition of Burghard's surgery.

The writer's observations lead him to conclude that chronic pancreatitis is usually, if not always, secondary to obstruction of the common duct; furthermore, that the prolonged, stormy postoperative recovery of some of the infected duct and gallbladder cases are due to chronic pancreatitis, and others to trauma inflicted at the time of operation by rough handling.

Disease of the endocrine glands, diverticulitis, sigmoiditis, tuberculosis, peritonitis, malignant neoplasms of the intestinal wall, incarcerated hernia, tabetic caries, cirrhosis of liver and kidneys, focal infections, and numerous other pathological conditions within and without the abdominal cavity will produce the symptoms which we have been discussing, but if sufficient has been said to direct your attention to the vast importance of extragastric lesions as causative factors in the production of surgical disorders of digestion, the writer's efforts and your time will not have been spent in vain.

WHAT HAS THE WAR TAUGHT US OF TUBERCULOSIS?*

By STEPHEN J. MAHER, M.D.,

NEW HAVEN, CONN.

CHAIRMAN OF THE CONNECTICUT STATE TUBERCULOSIS COMMISSION.

Recently I had an interesting conversation with an old acquaintance of yours and mine, the tubercle bacillus. I had just finished reading a very comforting address by one of our breezy western health officers on the approaching doom of the tubercle bacillus. According to this address, all that was necessary now to accomplish the destruction of the arch enemy of the human race was to quicken the social conscience and then to hand over this quickened social conscience to the various boards of health. The war, declared this address, had demonstrated that if tuberculosis were attacked army fashion there would soon be no tuberculosis.

Soothed and pleased at the prospect, I dropped the book for a moment and gazed rather vacantly toward the dwindling fire in the grate. I soon became conscious of a faint odor of violets in the room. I looked toward the door. There in front of me stood an enormous tubercle bacillus, curved and waxed, and glowing in a lethal haze of its own exuding. Like peas in a slender pod, four coccal granules shone dimly through its capsule. One of these coccal granules at the end of the bacillus nearest to me, was larger than the others, and seemed about to break out or bud, from the rest of the rod. Whether it was from this end that the voice came, I couldn't make out, but come it did, eery and gloating and defiant. And this is what it said:

"So, ho! The war has wrought my doom, eh? How downhearted I should be! Strange thing that while the war lasted I had more victims than ever before, more in the countries that fought, and more in the neutral countries. And since the war ceased, is there any country in the world where my deaths are fewer than before the war? But now I must prepare for my own death! I am to be no more! I am to be destroyed by army methods. Army methods! If the methods were good methods, undoubtedly the Army Medical Corps, because it is a well oiled machine, would get me, but the methods used by the American army, and, in fact, by every army engaged in the last war, to encompass my destruction, were ludicrous beyond description. The civil physician who examined the drafted men made some mistakes, but the army physicians who re-examined at the camps made more mistakes. The army method of physical examination was devised for the benefit of the feeble-minded of the army doctors to save them from thinking, but, of course, it applied to the able-minded of the army doctors as well. These it prevented from thinking. The resulting diagnoses were both tragic and comic.

"Army methods? Destroy me by army methods? The army methods of discovering me and my hiding places were worse than the pre-war civil methods. The *x*-ray? Yes! That helped the army somewhat, but the army merely used the imperfect pre-war knowledge, and the army use of this knowledge was frequently faulty because the colonel's interpretation of a plate was always right, and the captain's interpretation was right only when it agreed with the colonel's. The army *x*-ray machines added nothing to your knowledge of me, nor for that matter, to your knowledge of the *x*-ray.

"And, as to the army's method of treating my army victims, it was merely a stumbling and halting imitation of the civil methods of pre-war times —absolutely nothing new.

"And as to the army's method of keeping me from making new victims in the army—it had no such method. True, I didn't make many new victims in the army, but nobody in or out of the army knows why."

*Read at the New England Conference on Tuberculosis, Providence, R. I., Oct. 16, 1919.

Few New Cases in the Army.—"See here, you fiend," I cried, "in that last statement you admit that the army's methods were effective. You say few new cases occurred in the army. That was the object of all the army's methods—to prevent new cases in the army. And the same methods in civil life will prevent new cases in civil life."

"Ha, ha!" replied the voice. "The same methods have been long applied in civil life, and my power is still supreme the wide world over. And as to the effect on me of quickening the social conscience and handing it over to the various boards of health, there wasn't a regiment in Europe that didn't break all the board of health rules ever invented. The soldiers lived in insanitary quarters. They smoked incessantly. They drank wine and beer, and unprotected water and milk. They suffered hardships of all kinds, physical and mental. They spat on the walks and everywhere else. They slept in the mud. They were covered with cooties. They swapped pipes and clothes and knew not individual drinking cups. At the sight of these conditions, the members of the ordinary board of health, holding in their hands this precious quickened civic conscience that your friend talks of, would all have dropped dead of apoplexy.

"Yet, under these conditions few new cases of tuberculosis developed in the armies. The enormous increase in the number of new cases occurred in the comparatively comfortable, clean, well-housed people at home. Don't you think that the army's hardships, and lack of observance of board of health laws had something to do with saving the soldiers from tuberculosis?"

The log in the grate began to blaze. I heard a weird chuckle. I felt a little puff of breeze through the room. The odor of violets was swept away, and with it, the shape and the voice.

The Consumptives' Appeal.—And then the sounds of other voices filled the room. They were the voices of more than 1,000,000 people. They came from cabins on far away mountain sides, from midland mansions, from crowded city tenements, from sanatoria, from hospitals, from the learned and the ignorant, from the rich and the poor. They were the voices of the consumptives of America. And all the 1,000,000 voices cried in chorus: "Help!! Help!! Help us, O you doctors of tuberculosis. We are trying to do what you bade us do, but most of us are losing the fight. What is the secret of the enemy's power? Learn it quickly. Arm us against it. Help us or we perish."

At the beginning of the war, I read, with interest if not always with assent, the martial editorials in various medical journals, prophesying that one good, sure to come from the evil of the war, would be the solution of many medical problems, and particularly the problem of tuberculosis, because the thousands of doctors now being gathered into the army and navy would be able to make, so to speak, mass attacks on the problem, and they would not be wasting their time and energy on pitiful sniping from little laboratories. Well, now, here we are after the war—the first New England conference after the war—and face to face with the same tuberculosis problems as before the war. The war has not added one iota to our positive knowledge of tuberculosis. It has, perhaps, convinced the public that there is more active tuberculosis than had been supposed. But even the truth in that matter was recognized years ago. At the New England conferences at Springfield and New Haven, public bulletin asserted that every death in a community from tuberculosis meant as an average ten active cases of tuberculosis in that community.

New Knowledge Needed.—The war, it is true, has made clearer to us the poverty of our equipment for fighting the tubercle bacillus. The war has caused the making of comparisons, sometimes invidious, between the insufficiencies in equipment of states and countries. The war has taught many hundreds of young doctors the proper use of percussion and auscultation and the *x*-ray. The war has emphasized the need of hospital and sanatorium care for consumptives and the effectiveness of good nursing and of health propaganda. But beyond—nothing. Nothing concerning cause. Nothing concerning cure. Nothing concerning such questions as: Does tuberculosis always begin in childhood? Is it possible for a human being who escaped infection in childhood to contract the disease in adult life? Why are there more tuberculous men than women? Why does sunlight therapy usually cure bone and glandular tuberculosis, and usually fail to cure pulmonary tuberculosis? What happens to a child's organs and tissues when undergoing the sunlight cure of bone and glandular tuberculosis? Are all tubercle bacilli born of other tubercle bacilli? What is the relation to the tubercle bacillus of such acid fast bacilli as are found in dark barns, and as may be evolved from the spores of the ordinary beneficent bacilli of leaves and grasses? How dangerous to adult human beings is the milk of tuberculous cattle? Are tuberculous cattle always infected by other tuberculous cattle? What would happen if nontuberculous cows were made to live a year knee deep in manure, in new but dark, badly ventilated barns, such as are found on poor farms everywhere? What vaccinating power against human tuberculosis have the avian tubercle bacilli, the bovine tubercle bacilli, and the other acid fast or near-acid fast bacilli? What is the relation between tuberculosis and measles, scarlet fever, whooping cough, appendicitis, smallpox, gonorrhea, and syphilis? What is the explanation of the immunity of certain groups and individuals to tuberculosis? What is the explanation of grinder's and miner's tuberculosis? And the tuberculosis of the operatives in cotton, woollen, and silk mills?

The Framingham Experiment.—I have the honor to be a member of the committee in charge of the Framingham experiment, of which the director, Dr. Armstrong has told you. Nobody can have greater admiration for Dr. Armstrong and the things he is accomplishing than I have. One result of the Framingham experiment will be the improving of living conditions in Framingham and in every community that will copy Framingham's intensive health campaign. That result will mean the saving of many lives and the preventing of wastage of time and money. That result will mean that the Framingham experiment will have been well worth while. But, if that result be the only result, it will be to me, as the English say, "not good enough." I am of opinion such a result ought not to satisfy us in our fight with the flaming world-wide disease, tuberculosis. We must aim to stamp out the disease everywhere and for all time. Stamp it out

as yellow fever has been stamped out, or learn to control it as we have learned to control smallpox. To do this we need knowledge. This new knowledge we can get only by research. Until now research—particularly medical research, and more particularly tuberculosis research—has not had a strong appeal for young American doctors. Nevertheless, it is here in New England, the home of the Yankee, that many of the most important inventions and discoveries of modern times have been made. Why not get ready here to-day to awaken our young physicians of New England to the great opportunities that lie before them in tuberculosis work, opportunities for service, in most ways greater than are to be found in any other field of medicine.

In conclusion:

1. The war has taught us that the breaks in our knowledge of the tubercle bacillus prevent us from conquering the tubercle bacillus.

2. The war has taught the need of further tuberculosis research, and by implication has indicated that we who have the direction of the large sums of public money and the enormous amount of public enthusiasm now engaged in the antituberculosis campaign, owe it to the public to develop a greater and more intensive campaign of research than we have hitherto attempted.

3. The war has taught us that large medical military organizations are not capable of advancing our knowledge of tuberculosis, and that in the future, as in the past, we must put our dependence for results on the enthusiastic workers in the small wards and laboratories of hospitals and sanatoria and dispensaries, and on the observant physicians of private practice.

212 Orange Street.

CONCERNING HELIOTHERAPY IN TUBERCULOSIS.

By JAMES B. DINNAN, M.D.,

MERIDEN, CONN.

SUPERINTENDENT OF THE MERIDEN STATE TUBERCULOSIS SANATORIUM.

Our State Sanatorium at Meriden, located half way up the southern side of the Meriden mountain, and having an entirely unobstructed view of the wide Quinnipiac valley, gets more direct attention from the sun in the course of the year than most institutions in this part of the world. It also gets the most direct attention from wind storms, thunder storms, snow and ice storms. But that's another story. The important matter just now is the fact that it gets the most and the brightest sunshine. This fact doesn't give me the right to appear before you as an authority on sunlight, but it does give a partial explanation of why I have been interested in the subject of heliotheraphy during recent years.

The dictionary (Gould's) gives the following definition of heliotheraphy—"The treatment of disease by exposure of the body to sunlight. Sunbathing." I need not tell you that the use of sunlight in the treatment of disease is not new. It is older than civilization. And at some period and for some sickness, most civilized people have tried to practise it. The Egyptian doctors knew of it. Heroditus wrote of it. The physicians of ancient Greece and Rome made elaborate use of it in baths and solaria. In those old days, the sunlight treatment of disease was frequently part of a religious rite. For instance, the physician would send his patient to one of the temples of Apollo to pray for health. Apollo was the god of light and life. Temples to Apollo were built along the Mediterranean shore. To one of these, the patient came. The priests of the temple assigned him to one of the nearby cure galleries which were not unlike the verandas of a modern sanatorium (Baradat). Remains of these temples are still to be seen in the neighborhood of Nice. Our American Indians used heliotherapy and it is claimed that the Indians of Central America and of the Pacific Coast of South America used heliotherapy for the treatment of consumption.

So much of the contention concerning the action of heliotherapy impinges on the question of the effect of the various rays of the solar spectrum, that perhaps you will forgive me for recalling to your attention the fact that in estimating the wave lengths of these rays, the frequency of vibration of the red rays is estimated at 450 billions a second and the frequency of the violet rays at 750 billions a second, and the frequency of the ultraviolet rays at billions of billions a second; and that these ultraviolet rays are, perhaps mistakenly, called the chemical rays, and the red and infra red rays the heat rays, and the rays between, the luminous rays.

Malgat's rather fanciful description of the action of sunlight on the human body is as follows: "One portion of this bundle of white light is reflected into space; another portion pierces the skin as the solar spectrum, each refracted ray travelling and working on its own account. One transmits its own motion to the molecules and atoms of the skin, converts itself into work and thus extinguishes itself. Another portion penetrates into our internal organs, and there converts itself into molecular movement, and thus extinguishes itself. A third portion, a very small portion, not used by the skin, not used by our internal organs, goes through the entire body and loses itself in space."

Sersiron's summary of the action of light rays within the body is: "By their powers of decomposing and oxidizing, they destroy ferments, diastases, and microbes and the toxins of microbes, in the same way as they destroy moulds and mosses. And they are vasodilators and produce a passive congestion that greatly favors phagocytic action."

The present great interest in heliotherapy, especially in heliotherapy in tuberculosis, began only a comparatively few years ago. Even as late as 1905 at the great International Tuberculosis Conference held at Paris, the best authorities of France and the rest of the world regarded as unexplainable the mystery of the wonderful cures of bone and glandular tuberculosis that were taking place every day in the seaside sanatoria of France and other countries. Now, however, it is recognized everywhere that whatever assistance may have been given by the purity or salinity of the air, the salt water bathing, the ozone in the atmosphere, the sanitary environment, the good food, the important factor in the seaside cures of these

*Read at the meeting of the New Haven County Medical Society, Oct. 1, 1919.

cases of surgical tuberculosis, was sunlight. Before this, Finsen, of course, had been using sunlight for skin tuberculosis. And in 1902, Malgat, a physician of Nice, had read before the French Academy of Medicine his historic paper on heliotherapy. Then the physicians in charge of the famous sanatoria in the Alps began to take interest in the subject. Soon the whole world was taking interest in Rollier's demonstration that at Leysin, 5,000 feet above the sea in a place of perpetual snow, he could duplicate and surpass the best of the seaside cures of surgical tuberculosis. And his cures could, of course, be attributed only to sunlight. He pushed his belief far. He had his sun-brown crippled children, clad only in sandals, a hat, and a trunk, play games on the frozen snow. His dramatic successes threatened for a while to throw into the shadow the great work of the seaside sanatoria. Their final effect, however, has been to revive interest in the seaside sanatoria. Rollier and Leysin have merely explained the seaside cures, and caused the managers of the seaside institutions to develop in every possible direction the treatment of their patients with sunlight. Rollier's success has, of course, had the further effect of making it clear to physicians who have the misfortune to practise neither on snow clad mountain tops, nor on the ocean beaches, that sunlight is a powerful and badly neglected therapeutic agent even in such places as northern New York.

In 1913, I made visits to the largest of the sanatoria in England, Ireland and France that are devoted to the sunlight treatment of surgical tuberculosis, and I came home an enthusiastic believer in heliotherapy. The first seaside sanatorium to be erected in Europe for the treatment of glandular tuberculosis is still in operation. This is "The Royal Sea-bathing Infirmary for Scrofula" at Margate in England. It was founded in 1791, and has now 150 beds. For some reason or other, perhaps the scarcity of suitable beaches, England was not in recent years as enthusiastic about the seaside treatment of tuberculosis as most of the other countries of Europe. However, she has small sanatoria at such places as Bournemouth, Folkestone, New Haven, Brighton, Ramsgate, Scarborough, and St. Leonards-on-Sea.

Italy has more than twenty seaside sanatoria for tuberculous children, but most of them are not open in the winter. They care for more than 10,000 patients every year. Belgium's sanatoria at Middlekerke and Wenduyne are open all the year and have more than 200 beds. Only one small Dutch sanatorium is open all the year, the one at Loosduinen near the Hague. The others are at Scheviningen and Zandvoort and Wykaan Zee. Before the war, Germany's principal seaside sanatorium, the one at Norderney, was open all the year. It was founded in 1799, and treated more than a thousand children a year. Several thousand other children were treated during the warm months at a dozen other shore sanatoria. Austria, before the war, had seaside sanatoria on its bit of Adriatic coast, that cared for several hundred children. Denmark has four fine seaside sanatoria, three of them, Refsnaes, Juelsmunde and Odder, open all the year, and Helleback from April to October.

Norway has two seaside sanatoria open all the year, a large one at Freidrickvaern near Christiana and a small one at Hagewik near Bergen. In Sweden the sanatorium at Barkakra is open all the year and those at Styrso and Bygdea during the summer only.

Before the war Russia had three all-the-year sanatoria, Portugal two, Spain one, Argentine one, and the United States perhaps a half dozen. The pioneer in America was the one called Seabreeze and located on the Coney Island Beach in the midst of all the architectural and social jazz of that famous resort. The astonishing results achieved at this institution induced the City of New York to invest $2,000,000 for the purchase of a site and the erection of suitable buildings at Neponsit at Far Rockaway Beach. There is another all-the-year sanatorium at Atlantic City beside the Board Walk. And, as you know, Connecticut expects to open one at Crescent Beach, Niantic, during the next few weeks.

Thus far I have not mentioned the seaside sanatoria of France. I have reserved them for the last because they are the most important and because they have the largest and best digested reports. France has 15 of these institutions, 7 on the north coast facing the North Sea, the Channel or the Atlantic, and 4 on the Mediterranean. In the reports of 60,000 cases made to the Paris Congress, 74 per cent. of the gland cases were cured, 57 per cent. of the bone cases, 32 per cent. of the cases of Pott's disease, and 61 per cent. of the cases of tuberculosis of the skin, nose, eyes and ears, 72 per cent. of the cases of rickets. In the great sanatorium at Berck-sur-mer with more than 1000 beds, all the recent construction has been planned with the view of giving full sunlight treatment to all the patients, after the manner of Rollier.

It is important to remember that Rollier scorns the old method of bathing in sunlight only the affected part. His conception of heliotherapy is the bathing of the entire body in sunlight no matter how small or well localized the lesion may be. However, he makes the approach to a full sunlight bath very gradual. During the first few days the child is kept in bed and is not permitted to have any treatment. After three or five days, as a rule, he is pushed out onto the verandas into the sunshine. The head is covered with a white hat or an umbrella, the eyes protected with dark glasses, and a white garment worn over the body. On the first day the feet are exposed three times a day for five minutes; on the second day three times for ten minutes, and the legs to the knees three times for five minutes; on the third day the exposures are increased five minutes three times daily; on the fourth day the thighs are included; on the fifth day the arms; on the sixth day the back; and on the seventh day the abdomen and chest. By the end of the first week some parts of the body are exposed for one and one-half hours a day. The exposures are increased five minutes three times daily until the patient gets a full sun-bath for from three to five hours daily. This, as a rule, is the maximum, although some

bear the treatment for seven hours. Individualization, of course, is necessary and in some instances the scheme of exposures must be modified to suit the case. Pulse and temperature are closely watched and used as indicators of the patient's tolerance.

At the last International Conference on Tuberculosis, the one held in Berlin in 1913, there was considerable discussion as to whether sunlight therapy, on snowy mountain tops or on the white beaches of the ocean gave the best clinical results. The advocates of the seaside proclaimed instances of cures in patients that had done badly at Leysin. And diametrically opposed claims were made by the physicians from the mountains. Much of the discussion centered on the question of what it was in sunlight that was curative. We have seen that sunlight cures cases of surgical tuberculosis not only at the seashore and on snowy mountain tops, but also in less suitable places. How does it do it? As the French say, what is the mechanism? Ah, there is a big question! And it deserves an answer. On that answer depends the other question—If sunlight cures bone and glandular tuberculosis so easily, why does it usually fail to cure pulmonary tuberculosis? It was believed by Finsen, who was one of the first to make a serious effort to use sunlight in tuberculosis, that the ultraviolet rays of the spectrum were the only ones having curative power, and, that as the ultraviolet rays stopped at the skin it was useless to expect any effect from sunlight beyond the skin. His conception of his cures of lupus and other superficial tuberculous lesions was that the chemical ultraviolet rays killed the germs, but were absorbed by the hemoglobin in the superficial blood vessels. Therefore, his use of arc lamps and crystal. Therefore, also, most of the patented lamps made in Germany, and guaranteed to be more efficacious than sunlight because of their giving off more ultraviolet rays than most sunlight.

There was in the beginning a tendency everywhere to ascribe the remarkable cures of Rollier to the fact that there are more ultraviolet rays in the light on the snowy mountain tops than in the lowlands. Now, however, these views are generally discredited, even at Leysin.

Occasionally even now, somebody refers to the ultraviolet rays as the important factor in sunlight therapy, and holds to the theory that the browning skin of the patient changes the short chemical waves into longer light or heat waves. There doesn't seem to be much foundation to such a theory. Confessedly, we don't yet know for sure how sunlight acts when it cures surgical tuberculosis. But in view of what we do know, it seems fair and safe to consider that all the rays of the spectrum are needed to produce the best effects. Baradat, in the course of an argument against the advocates of the ultraviolet theory, has the following gallic pargaraph:

"Although there does not exist any practicable method of establishing the proportion of ultraviolet rays in any given atmosphere, it is easy to show that really everything in nature puts itself in a state of defense—for the protection of the human organism and for the protection of every living thing, and for the protection of the earth itself—against the radiation of the ultraviolet rays. The ozone which is formed at the first contact of the sun's rays with the oxygen of the highest regions of the earth's atmosphere, becomes immediately a halting place where many of the chemical rays are absorbed and those that remain become fewer and weaker, metre by metre, as they proceed through the 50 or 60 kilometres, that they must traverse before they reach the surface of the globe. The very skin of men and animals turns brown and covers itself with pigment in order to save itself from penetration by the radiation of the ultraviolet rays. 'And finally,' as said Nogie, 'if the ultraviolet rays could penetrate to the surface of the earth, they would bring about the immediate destruction of all vegetables and animals. Apollo, god of life and light, would be overwhelmed by Pluto, the King of hell.'"

Of course, the ultraviolet rays can kill bacteria but they cannot penetrate the skin. And the more the skin is browned, the more resistent is it to ultraviolet rays. But the browning of the skin in heliotherapy is universally recognized as an indication of the success of the treatment. The patient whose skin does not become brown and remain brown, causes immediate anxiety to his physician and nurses. One of the remarkable reactions of sunlight therapy is the exhilarating or tonic effect that it has on the patient. Ultraviolet rays are not stimulating. They are destructive of life. And it has been shown by many experimenters, even by Rollier, that the sunlight does penetrate the human body and that the depth of the penetration is dependent on the intensity of the sunlight. Malgat claims that with intense radiant sunlight alone, he has been able to get on a sensitized plate, an impression of a human chest. Yet the ultraviolet rays, because of their shorter waves, are stopped by the first layer of skin they touch, while the other rays of the spectrum, because of their greater lengths, penetrate the body more and more deeply the nearer they are to the red end of the spectrum. It would seem to be fair to assume from our present knowledge of the subject, that all the rays of the spectrum, the heat rays, the light rays, and the chemical rays, are of importance in heliotherapy, particularly in heliotherapy of tuberculosis. As I have said, the authorities of the Swiss mountains admit that much.

Morin of Leysin, one of Rollier's coworkers, in discussing the question of the place most suitable for administering heliotheraphy to the tuberculous, decides as follows: "Nobody can deny that the Alpine climate is one of the best for the purpose of heliotherapy. Here heliotherapy can be practised the whole year around. Here the sun's rays are strong, and here the air is fresh and cool. The seaside is equally suitable for the sun cure, because here the rays of light, refracted by the shining water and by the sandy stretches of beach, acquire increased intensity. In the lower lands of the middle of Europe, it is possible to practise heliotherapy in the summer time, but even then it is less efficacious than on the mountain tops because of the absorption of so much useful light by the impurities of the atmosphere."

Rollier reports from Leysin the remarkable figure of 79 percent. of cures in his cases of tuberculosis of the vertebrae. Hertz, the superintendent of one of the seaside sanatoria in Denmark, who for the last five years has been giving heliotherapy in full measure to his patients, summer and winter, has just published some results that not only rival Rollier's, but show that with the development of the possibilities of heliotherapy, the results achieved in the old days by the French seaside sanatoria can be greatly improved. His cures of tuberculosis of the vertebrae have been 75 percent. of 271 cases; tuberculous hips, 90 percent. in 139 cases; tuberculous knees, 97 percent. in 74 cases; tuberculosis of the mesentery, 94 percent in 61 cases; tuberculous adenitis, 95 percent. in 248 cases; multiple tuberculosis of bones and joints, 73 percent. in 11 cases. He claims that the cure has been permanent in a much larger number of cases than in the best surgical statistics, and he quotes approvingly Calot's dictum on surgical tuberculosis, "Le bistouri, c'est l'ennemi."

Thus far I have not spoken of the use of sunlight in the treatment of pulmonary tuberculosis. Not that I haven't had it in mind. In fact, that is the phase of the subject that interests me most. Practically all of my patients are cases of pulmonary tuberculosis. When I read four years ago that Rollier claimed that by his methods of using heliotherapy he had cured not only surgical but also pulmonary tuberculosis, I decided to start a little heliotherapy clinic with some of the consumptives under my care at the Meriden Sanatorium, and in the treatment to follow closely Rollier's technique. The class consisted of six male patients ranging from fifteen to fifty-four years of age. All were active advanced or second stage cases. All had tubercle bacilli in their sputa. The experiment was begun in early June, and continued until the end of October. It was conducted on the roof of one of our second story verandas. I followed the gradual exposure methods of Rollier. For two patients we went a little too fast in the beginning, and as a result had two sharp sunburns. These soon healed, and in ten days the two patients had caught up with their classmates. Except for the slight inconvenience, due to sunburn, none of the patients experienced any discomfort at any time. The patients were exposed while lying on cots placed on the veranda roof. The amount of body surface exposed was controlled by the use of a light covering. The equipment of each patient consisted of a pair of light cotton drawers, a white hat and a pair of smoked glasses. The treatment was continued for five and one-half months, but exposures were made only on 107 days, owing to the many days of rain and showers which necessitated a discontinuance of treatment for the day. The atmosphere varied between 40° F. and 90° F.

Determinations of blood pressure, counts of the red and white blood corpuscles, and estimations of hemoglobin were made at first every few days, and later every week. The patients were weighed weekly, while temperature, pulse, and respiration were taken daily at the beginning, and ending of exposure. Frequent notes were made as to cough, amount of sputum, appetite, sleep, and condition of the bowels. Several examinations of sputum were made during this period. At the beginning of treatment, radiographic plates were obtained in each case.

I have reported in a previous paper read at one of our conferences of the staffs of the State Tuberculosis Sanatoria, the tabulated results of all these observations. To-day, I will give you merely the general summary:

Of the six patients, two are dead; three are arrested cases, and have returned to work. The sixth patient left the sanatorium an arrested case and returned to work, but I have not been able to trace him for the last two years. Of the two who died, one left the sanatorium improved and died eighteen months later of a severe hemorrhage; the other died at his home. He had a greatly hypertrophied heart, but it was undoubtedly his tuberculosis that killed him. For these six patients, the five and one-half months of heliotherapy lessened the sputum in all cases; markedly improved the cough in five cases; improved the temperature in two cases; slowed the pulse rate in four cases; browned the skin in all cases at first but in the two who died later, the skin paled in patches after thirty days and never again darkened; sleep was better and appetite better in all cases; all said they felt better; four cases lost weight, an average of 2¾ lbs.; two cases gained weight, an average of 7½ lbs.; two of those who lost weight were among the arrested cases; the records of our hundreds of observations of blood pressure, red and white blood counts, and hemoglobin estimations showed no apparent relation between these results and a gain or loss in general or lung condition.

This summer, we happened to get among the new admissions of children, several acute cases of bone and glandular tuberculosis. It occurred to me that it would be worth while both for the patients themselves, and for the sake of comparing results, to subject them to a Rollier regime of heliotherapy for a few weeks. I am having three of these children brought to the meeting today for your inspection, not because the results are any more wonderful than those secured at other sanatoria, but to allow you to visualize some of the reactions of the Rollier treatment.

In conclusion, I would say:

1. Sunlight properly applied is our best therapeutic agent in the treatment of bone and glandular tuberculosis.

2. Although sunlight therapy has been most successful when applied to patients on mountain tops or on ocean beaches, it gives also excellent results inland and on the lowlands.

3. Although the number of cases of pulmonary tuberculosis that I treated with systematic heliotherapy was too small to permit the drawing of conclusions, it has left me with the conviction that the general skepticism on this subject is not warranted, and that we owe it to the public to take a much greater interest in the possibilities of heliotherapy in pulmonary tuberculosis.

4. A promising field for future research in our scientific laboratories would be intimate studies of the effect of heliotherapy on the tissues and organs of diseased and healthy animals.

TREATMENT OF INFLUENZA BY AN APPARENTLY SPECIFIC METHOD.

By FRANCIS E. PARK, M.D.,

STONEHAM, MASS.

In the March 6, 1915, issue of the MEDICAL RECORD I published a treatment which I had found to be of the greatest value in lobar pneumonia. As the subsequent years had fully borne out its earlier

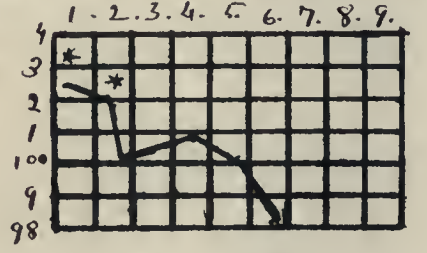

FIG. 1.—Case I.

promise both in my own practice and in that of other physicians who had adopted it, on the advent of the influenza epidemic, with its very frequent complication of pneumonia, it seemed to me to be a

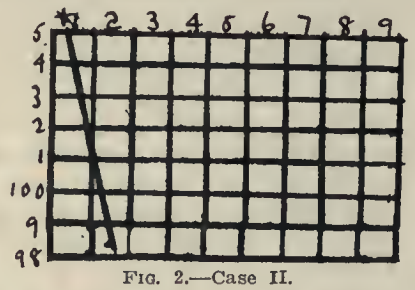

FIG. 2.—Case II.

most logical treatment and was used throughout the entire run of the disease, giving me prompt and uniform success in every indicated case.

I will first give a brief history and the tempera-

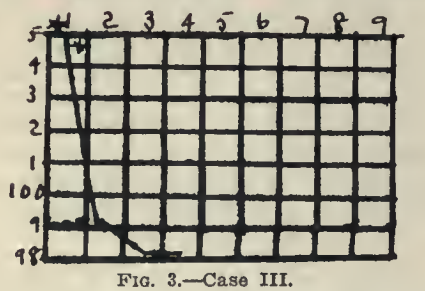

FIG. 3.—Case III.

ture chart of 30 consecutive cases, which are typical of all those treated, and then describe again the method used. An asterisk on the chart signifies an injection.

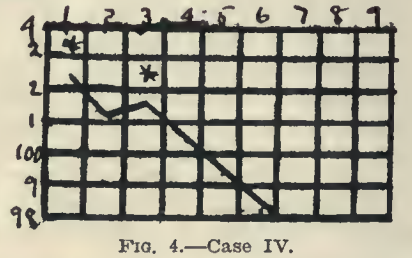

FIG. 4.—Case IV.

CASE I.—Mrs. V., 61 years. Very fat, much prostrated, great congestion of lungs, with rusty sputum and beginning consolidation. Tendency to asthma. Perfect recovery. Two injections of 4 c.c. each.

CASE II.—Man, 38 years. Was taken ill late in the afternoon; I saw him at midnight; typical case. All symptoms very pronounced. One injection was given of 5 c.c. The patient was discharged the following day.

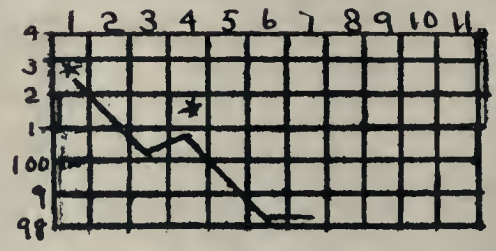

FIG. 5.—Case V.

CASE III.—Man, age 25. Very violent sudden attack. He fainted at his work. I saw him an hour later, and gave him 5 c.c., following this with another 6 hours later. Immediate recovery.

CASE IV.—Woman, 35. Very septic case. Did not respond promptly; yet did not get worse, but recovered more slowly than some. Had two injections.

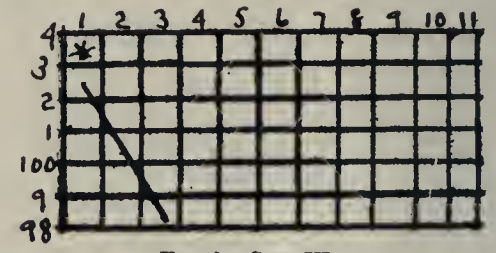

FIG. 6.—Case VI.

CASE V.—Woman, aged 45. Moderately sick when seen. Two injections of 3 c.c. each were followed by perfect recovery.

CASE VI.—Man, aged 31. Beginning case. Well marked symptoms, moderately advanced. He made a good recovery after one injection of 4 c.c.

CASE VII.—Man, aged 28. Had been sick but a few

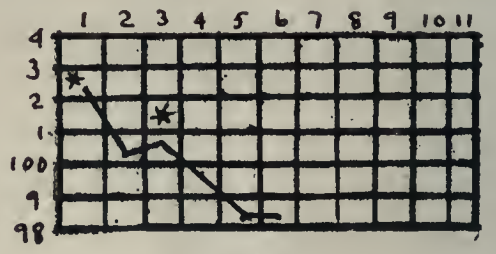

FIG. 7.—Case VII.

hours. Bronchial symptoms were very pronounced and there was apparently a beginning pneumonia as well. The patient was badly run down by overwork. I gave him two injections of 4 c.c. each. Good recovery.

CASE VIII.—Man, aged 33. Beginning case. All symptoms were well pronounced. One injection of 4 c.c. was followed by prompt recovery.

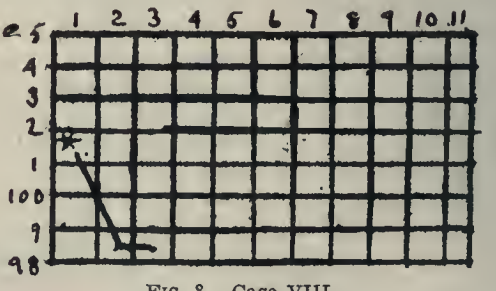

FIG. 8.—Case VIII.

CASE IX.—Boy, aged 19. Had been sick about 8 hours, and was very much prostrated. There was intense congestion of both lungs. He received one injection, and rapid convalescence followed.

CASE X.—Man, aged 27. Light case, did not have to go to bed. One injection of 3 c.c. was followed by immediate recovery.

CASE XI.—Woman, aged 31. Had been sick 2 days,

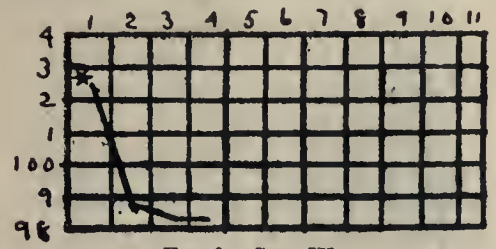

FIG. 9.—Case IX.

and was greatly prostrated. There was some consolidation in one lung. This was the type of case that often ended fatally. I gave two injections of 3 c.c. each.

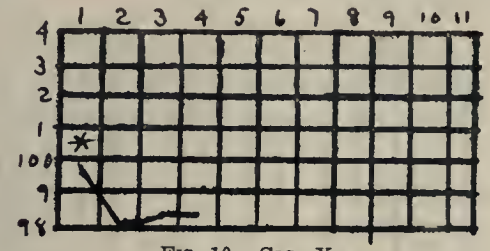

FIG. 10.—Case X.

CASE XII.—Girl, aged 16. Seen soon after the onset. Extremely ill. One injection of 3 c.c. was followed by good recovery.

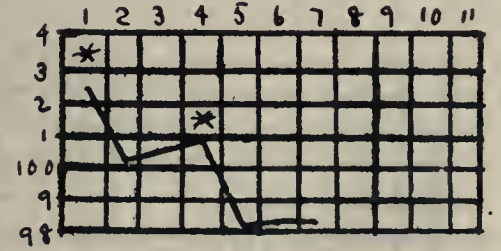

FIG. 11.—Case XI.

CASE XIII.—Girl, aged 19, very fat. She was extremely ill, presenting the appearance of the fatal type

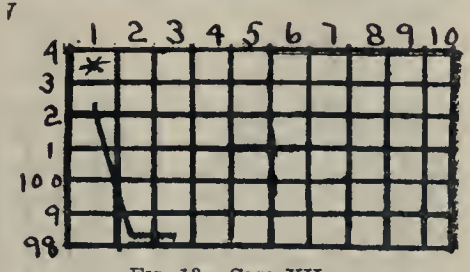

FIG. 12.—Case XII.

of influenza, the symptoms being exaggerated. One injection preceded a prompt recovery.

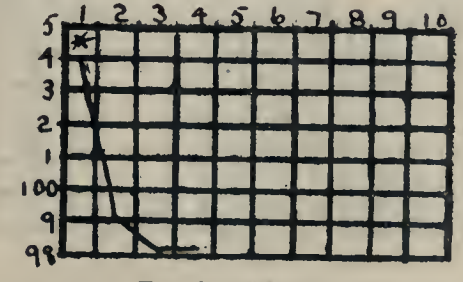

FIG 13.—Case XIII.

CASE XIV.—Man, aged 52, very heavy build, full blooded. He had great congestion of the lungs, with marked prostration. A good recovery followed one injection of 4 c.c.

CASE XV.—Boy, aged 18. Beginning case. Very ill. One injection. Good recovery.

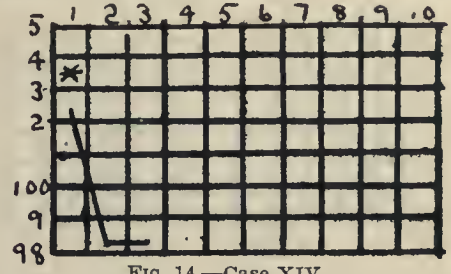

FIG. 14.—Case XIV.

CASE XVI.—Man, aged 51, a debilitated alcoholic. Marked pulmonary congestion. Extremely ill. He received one injection of 4 c.c.

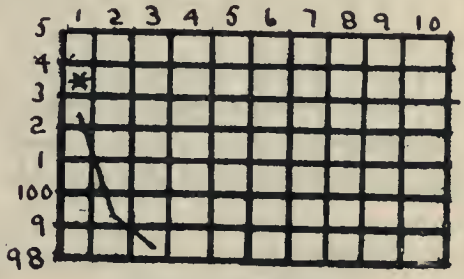

FIG. 15.—Case XV.

CASE XVII.—Girl, aged 19. Had been sick 2 days. She responded well to the first injection, but after a sharp drop in the symptoms, the temperature started

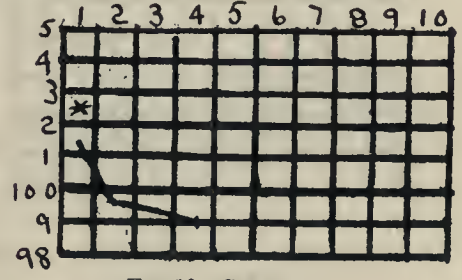

FIG. 16.—Case XVI.

up again, necessitating a second injection, when it immediately began to fall, and the patient made a good recovery.

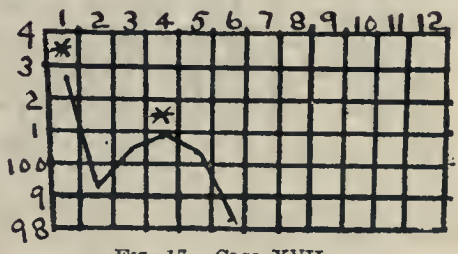

FIG. 17.—Case XVII.

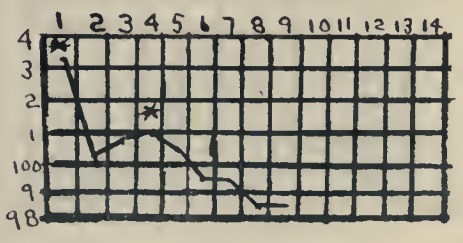

FIG. 18.—Case XVIII.

CASE XVIII.—Woman, aged 26. Much run down, showing but little resistant power. She responded

promptly at first, then after a slight rise of temperature made a slow but steady gain. There was slight pneumonic process in one lung. The patient received two injections of 3 c.c.

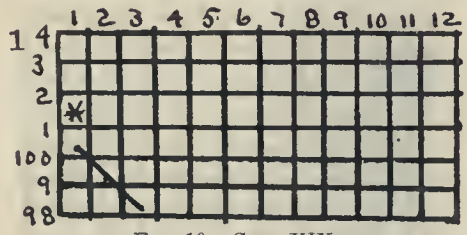

FIG. 19.—Case XIX.

CASE XIX.—Man, aged 20. Early case, not well developed. Had one injection of 4 c.c., which was followed by immediate improvement.

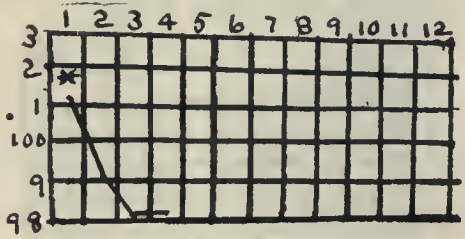

FIG. 20.—Case XX.

CASE XX.—Woman, aged 23. Very sick. I saw her about 8 hours after the onset of her illness. She was

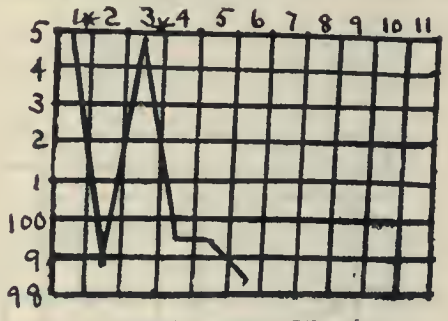

FIG. 21.—Case XXI.

having great pain and prostration. One injection of 4 c.c. was followed by a good recovery.

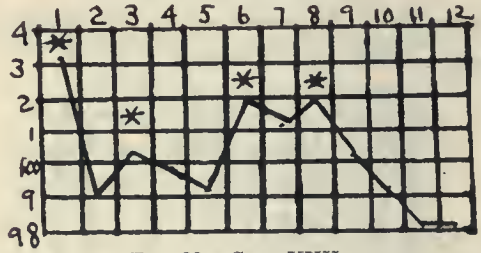

FIG. 22.—Case XXII.

CASE XXI.—Nurse, aged 24. Very severe attack complicated with acute otitis media. The drum mem-

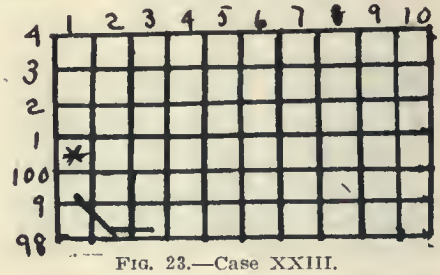

FIG. 23.—Case XXIII.

brane was punctured at once, and an injection of 4 c.c. was given. Immediate relief followed, but in a few hours the temperature shot up again accompanied with a severe chill. The ear was draining freely. A second injection was given with marked relief. The patient made a good recovery.

CASE XXII.—Girl, aged 20. Very sick. Responded nicely at first, then a pneumonia set in running a very

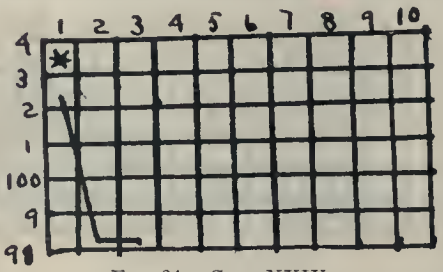

FIG. 24.—Case XXIV.

mild course. At no time did she appear to be in any danger, and eventually she made a good recovery. She received four injections of 3 c.c. each.

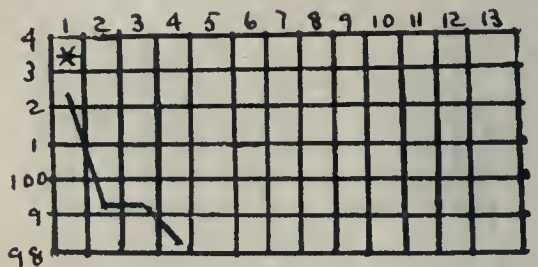

FIG. 25.—Case XXV.

CASE XXIII.—Girl aged 20. The attack had just begun and had not gained much headway. One injection of 3 c.c. was followed by immediate recovery.

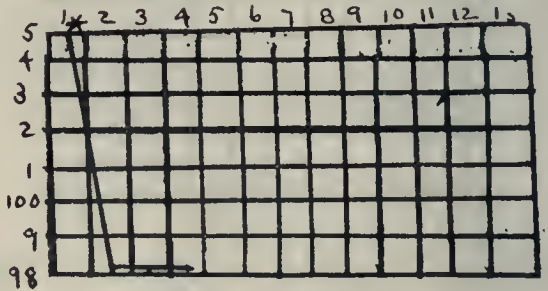

FIG. 26.—Case XXVI.

CASE XXIV.—Woman, aged 34. Very fat, and extremely ill, showing the symptoms of the rapidly fatal

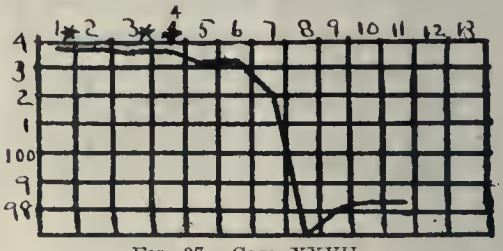

FIG. 27.—Case XXVII.

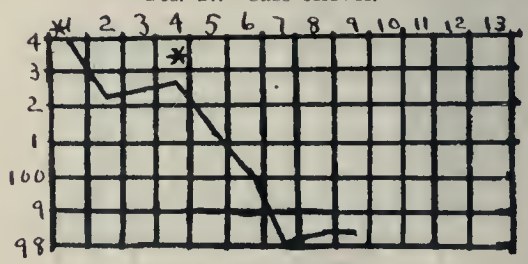

FIG. 28.—Case XXVIII.

type. The patient was greatly alarmed by her condition. I gave her one injection of 5 c.c. with the result that the patient was discharged the following day.

CASE XXV.—Man, aged 25. Fully developed attack ac-

companied by marked prostration. One injection of 4 c.c. was followed by a good recovery.

CASE XXVI.—Man, aged 35. He was seen 6 hours after the attack began, and was at that time very sick, all the symptoms pointing to a beginning pneumonia. I gave him 5 c.c. and the man was well the following morning, and was back at work in 2 days.

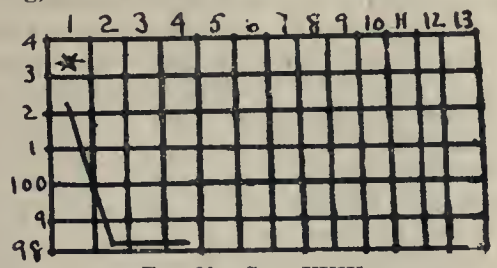

FIG. 29.—Case XXIX.

CASE XXVII.—Man, aged 25. Influenza with double lobar pneumonia. I am absolutely sure that under the usual treatment this man would not have lived 3 days. One of the most desperately ill patients I have ever seen. He received three injections of 5 c.c. each, and made a very good recovery.

CASE XXVIII.—Insane woman, aged 23. The influenza was complicated from the start with lobar pneumonia. It was naturally a difficult case to handle. The patient received two injections of 3 c.c., the second being followed by recovery.

CASE XXIX.—Man, aged 34. The onset was severe and the man was very sick. I saw him 6 hours after attack began and gave one injection of 5 c.c. The temperature fell rapidly and recovery ensued.

CASE XXX.—Man, aged 31. Double lobar pneumonia had already started when I saw the case. I gave three injections of 5 c.c. each. Convalescence began in four days, following the third injection. This man would in all probability have died under the ordinary method of treatment.

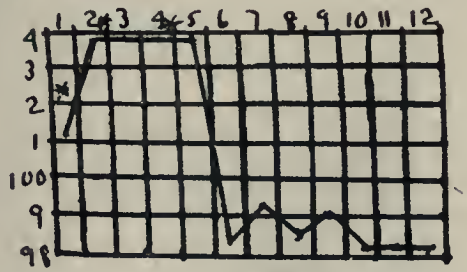

FIG. 30.—Case XXX.

On looking over the charts, one is struck by the constant fact that there is almost invariably an immediate drop in the temperature after the injection is given. This was constant through the whole epidemic. It applied, however, only to those cases seen fairly early, say within twenty-four hours of the onset of the attack. I saw many cases in consultation where the patients were cyanosed or nearly moribund, and in these there was no response. They seemed to have lost the power to react. Apart from these late cases, all those I saw recovered promptly and without complications. Another remarkable thing was that I did not see a cyanosed case where the treatment was used promptly. In treating the cases I not only made use of this specific intravenous treatment, but in addition, I kept the bowels open and also used the spirit of nitrous ether to assist elimination through the kidneys, giving small doses, from 10 to 20 drops every two hours in plenty of water. This I consider of great importance as an aid.

The treatment is very easy to give, any physician who can insert a hypodermic needle into a distended vein can give it.

I prepare my solution as follows: Dissolve in 60 c.c. of physiological salt solution, 1.3 grammes each of sodium salicylate and soluble iron phosphate. Filter this and sterilize with heat. Then add 1 c.c. of a saturated solution of the best beechwood creosote in lime water. The solution is then ready for use. The dose varies from 3 to 5 c.c. and can be repeated in twelve hours if needed. I have never given more than four injections in any one case, and the great majority required but one.

Great care must be taken to put the injection into the vein. If it is deposited in the arm much pain and disability will result. There should be absolutely none if it is given right. If the needle is inserted properly it will be possible at any time to prove its position, by withdrawing the piston of the syringe slightly, when the blood can be seen pouring into the barrel. One should always use an all-glass syringe and insist on having one with the nipple on the side, rather than on the middle of the end of the barrel, as is usual. The advantage of this is twofold: First, it is much easier to insert; and, secondly, it gives one a larger margin of safety, in case a bubble of air has gotten in through a poorly fitting needle, and one does not wish to remove it at the time; for until all the solution has been injected the air will stay in the top of the barrel and one can easily control it.

The injection should be given very slowly and through a 26-gauge needle; a steel needle can be used perfectly well, and has the added advantage of a sharper point.

The only reaction that will be observed comes at once. First there is a flushing of the face, quickly followed by nausea, and in some cases, emesis. It is all over as quickly as it comes and nothing further is felt. It is well to explain this to the patient, so as to prevent any alarm on his part.

In conclusion I wish to emphasize that the great point of this treatment is that it must be used promptly—as soon after the onset of the disease as possible. The patient rapidly loses the power to react. I should not hesitate, however, to use it at any stage, for in the many thousand injections I have given, even in very aged and weak people, I have never seen any harm occur. But it is pre-eminently a treatment to abort and cure the disease in the early stage. In six years' constant use I have never seen it fail when given at this time.

The Professorship of Medicine held by Laennec in the University of Paris.—This chair was founded in 1542 and has had fifty incumbents up to the present time, an average incumbency of seven and a half years. Distinguished in their day were nearly all of them but not many names mean anything to us now. Some of the more distinguished up to Laennec's time were Guy Patin, Riolanus, Tournefort, Ferrein, Portal, Astruc, Corvisart, Hallé. Yet by some irony of fate hardly one of the men mentioned is remembered as a physician, for Patin is best known as a satirist, Riolanus as a botanist, Tournefort as a traveler and botanist, while Ferrein and Portal are known to us to-day only as anatomists. Corvisart was, of course, Napoleon's physician and with his pupil Laennec marks the transition from prescientific to scientific days. Even Recamier, who succeeded Laennec, hardly belonged to the new regime. But at a later period we find the chair of Laennec filled by Magendie, Claude Bernard, Brown-Sequard, d'Arsonval; all eminent, but rather as physiologists than practitioners.—Letulle in *La Presse Médicale.*

New York, January 10, 1920.

PREVENTIVE MEDICINE IN GREAT BRITAIN.

IT seems to be generally admitted that medical practice is now in an evolutionary stage in Great Britain. Old conceptions as to the duties of the general practitioner are being very considerably revised if not cast aside entirely. The work of the medical profession in Great Britain in the future will consist rather in the prevention than in the treatment of disease. The creation of a Ministry of Health is the straw which shows the way the wind is blowing. Up to the present time the Ministry of Health does not appear to have done any practical work, but it has done a good deal of clearing the ground, preparing for practical work. With this end in view the Minister of Health has caused the experts who are members of his medical staff to issue a series of memorandums. Perhaps the most valuable of these yet sent out is that recently issued by Sir George Newman, Chief Medical Officer of the Ministry. In this he discusses the functions and practice of preventive medicine and indicates the lines on which should be developed the great work of conserving and improving the health of the nation. It is pointed out that the chief business of the practising medical man is to cure disease; the primary function of the State in relation to disease is to prevent it. While these two spheres overlap in the routine of daily work, they possess a firm, common ground in research, upon which prevention and cure very largely depend. Of course, the population of Great Britain is very much more dense than it was in the last century, and in addition the stress and strain of modern life, reacting on body and mind alike, have become so intense as to produce diseases formerly unknown. Up to quite recent times the State had concerned itself little with questions of health, with the exception of the supervision of certain dangerous trades. Despite this negligence the population has become progressively and steadily more healthy and the span of life has been increased. This so far satisfactory state of affairs may be traced in the main to an enlightened public opinion, led and fostered by some of the pioneers of sanitation, which has found expression through the popularly elected local governing bodies responsible for the management of sanitary matters.

This is the bright side of the medal, but there is, of course, a reverse side. Statistical data reveal the following facts, or one might preferably say broad deductions: (1) There is a steadily falling birth rate. (2) There is a death rate which shows a steady decline at all ages, and there is an increased expectation of life from birth upward; nevertheless, nearly half the deaths occur under 50 years of age. (3) Although the infant mortality rate is one of the lowest recorded, there is still unnecessary loss of life in infancy and before birth. (4) There is a relatively light burden of epidemic and infectious disease, which, with certain exceptions, is steadily decreasing in incidence and mortality, an indication of the progress of preventive medicine. (5) Tuberculosis, measles, acute rheumatism, and influenza are, however, still prevalent, and, with venereal disease, lead to much disablement and mortality. (6) There has been in recent years remarkable and continuous improvement in sanitary environment, though the problem of insufficient and unsuitable house accommodation remains. (7) The systematic medical examination of school children since 1908 has revealed a substantial degree of physical and mental impairment, both the existence and effects of which have been confirmed by the examination of recruits. (8) The expenditure on sickness and disablement benefit, and other returns related to the system of national insurance, denote that more than half of the insured persons claim and receive treatment, and that a very serious amount of time is lost to employment, amounting to upward of 270,000 years per annum, owing to invalidity or disablement, much of which is preventable.

The problem, then, lying immediately before preventive medicine is, first, to rear and maintain a healthy race of people, and, secondly, to continue the attack upon infection and to initiate an attack upon all forms of preventable sickness and invalidity. The provisional articles of a national policy in preventive medicine are thus outlined: Eugenics and the principles of sound breeding; maternity and the care, protection, and encouragement of the function of motherhood; infant welfare and the reduction of infant mortality; the health and physique of the school child and adolescent; sanitation and an improved personal and domestic environment; industrial hygiene; the health of the worker in the workshop; the prevention and treatment of infectious disease; the prevention and treatment of non-infectious disease; the education of the people in hygiene; research, inquiry, and investigation; and the extension of the boundaries of knowledge.

It is clear that if the policy of the Ministry of Health of Great Britain is carried out on the lines indicated in the memorandum, a large proportion of the British medical profession will be practising preventive medicine and must be educated accordingly. It is patent that such a policy calls for an adequate medical service and appropriate administrative machinery. It will not be the highly skilled consultant who is in the front rank in the nation's

fight for health, but the main body of the profession. The medical profession of Great Britain will have to reform its methods of medical education and the hospital service must be reformed also. At least, this is the opinion of the writer whom we have quoted. America has not a central department of health, but sanitary and health conditions in Great Britain and America are closely alike in many respects. It should therefore be instructive for the medical men of this country to watch those of Great Britain proceed along a new path, more especially as we may have to travel along the same path in the not far distant future.

CONCERNING NECROPSIES.

THE subject of necropsies is one of such vital importance to our profession that we have no hesitation in adding our voice to that of Dr. Douglas Symmers, who, in a recent article in the *Journal of the American Medical Association*, deplores the difficulty of obtaining necropsies in a State like New York. Although, as Dr. Symmers points out, medical men still exist who are indifferent to the value of necropsies, there is no question that the laity need far more to be educated in that regard. Many a medical man would be willing to travel far to learn the exact nature of a lesion which has long been a puzzle to him. But he is all too likely to be met with, "Cut him all up? Never!" Vain are his pleas of "value to science," "no mutilation," "no desecration." Science failed to save the life—now science can go hang. The words autopsy and post-mortem still connote "cutting up," hacking the beloved remains.

The medical profession has been slow to educate the public to the real service which their dead bodies can perform. Legislation can and should deal with the profitable disposition of bodies which no relative cares to bury. But when we deal with beloved dead instead of unwanted derelicts, legislation must keep hands off, and only individual enlightenment should control. Before the people can be expected to co-operate in the matter of granting permission for necropsies, they must first be taken into the confidence of the doctors. Often the more intelligent will grant such permission on the promise that the findings will be reported to them. Surely it is but seldom that such information need be denied them. At present the laity know only that necropsies mean mysterious tampering with the dead. They may even admit that necropsies are a help to medical science. They have yet to learn what pathology can do for themselves.

Perhaps it is the medical man's sense of pride which is to blame for the public's ignorance of what the pathologist can contribute to its physical welfare. The doctor is painfully aware of the frequency with which the pathologist makes havoc of his sense of conceit. Fallibility is something which his patient must by no means suspect in him. Laymen will condemn more harshly than pathologists, and often with less reason. But necropsies are essential to honest medicine. The real scientist need not be ashamed of his mistakes—if he does not make them too often.

DATE OF ORIGIN OF THE INFLUENZA PANDEMIC.

BETWEEN the actual and apparent dates of an epidemic there may be a considerable interval. This was seen in connection with the outbreak of syphilis in Italy in 1494. Without any reference to the American origin of the disease it has become apparent as a result of cumulative study of certain town archives, not only that no sudden invasion of this disease could have occurred at the times and places stated, but that the condition was not in reality a new one and can be traced backward haltingly until it is lost in medieval obscurity. The fact that the earliest town archives go back only to the middle of the XVth century is largely responsible for this state of affairs.

In regard to the influenza pandemic it is not long since that writers appeared to agree that the outbreak could not be traced back of the Madrid episode in the last week of May, 1918; yet already we note that the pandemic has been traced to March of the same year and in both France and Italy. Dr. Rho, at the head of the Italian Military Marine Medical Department, in a report first made last March before the Inter-Allied Sanitary Commission, recalls the appearance as early as March, 1918, of cases in his service, nor does he call them three-day fever but influenza. Calmette at the same meeting fixes March as the first month of diffusion of the pandemic. However, we know now, no more than before, where was the cradle of the disease. Dr. Siredey, head of the Hôpital St. Antoine in Paris, states that the first cases of influenza appeared during the month of March and that the institution has never since been free from cases. The fact that outbreaks of grippe occurred in the United States in March, 1918, may also be recalled. When the disease first attacked Europe it was seriously stated that the infection had been brought from America, in which country it had broken out among the prisoners at Sing Sing in March.

Any grippe which breaks out in the late Spring should clearly be regarded with great suspicion because what is known as influenza nostras, acute catarrhal fever, and endemic winter grippe is strictly a seasonal affection which begins with cold weather. As far as we can see now the influenza originated in March and several months were required before it gained sufficient headway to assume pandemic incidence.

SYPHILIS AND TUBERCULOSIS.

SYPHILIS, the arch enemy of mankind, not only modifies, and usually for the worse, the course of many diseases, but also, undoubtedly, prepares the soil for numerous infections which otherwise might have been successfully resisted. We are reminded

again of this by an article on the association of syphilis and tuberculosis appearing in the December issue of the New British monthly journal *Tubercle*. In this article Dr. Alfred Mirande of Paris points out that Emile Sergent by a series of experiments has not only confirmed the views of those who have shown that there is an association between syphilis and tuberculosis, but has placed the matter in a somewhat new light. Sergent's thesis is thus summarized by Mirande: Syphilis and tuberculosis are two different infections and can develop separately in the same organism. Syphilis produces a soil for the tuberculization of the infected subject, but especially does the syphilis of the father prepare for the tuberculous infection of his child. Many forms of tuberculosis, and in particular scrofula, develop most often in a favorable syphilitic soil. Perhaps the most interesting and suggestive part of the article is that which deals with the subject of tuberculosis in cases of congenital syphilis. According to Sergent, tuberculosis in a young congenital syphilitc, instead of taking on the bronchopneumonic form general in subjects of this age, develops as an excavation, the cavity being either the product of associated action of the treponema and the tubercle bacilli or of the bacilli only. In any case mercurial treatment should be commenced and will help the cicatrization of pulmonary lesions, even when the bacillus of Koch is present. In the case of a congenital syphilitic apparently without lesions, the phthisis becomes sclerotic, and as in the adult is accompanied by asthma and emphysema. Finally, Mirande remarks, it should be remembered that the frequency with which syphilis is found in the children of tuberculous parents, whoever they may be, has prompted Sergent to wonder whether tuberculosis is not often the indirect result of the inheritance of syphilitic soil, and to put forward his claim that tuberculosis may be a symptom of congenital syphilis. In making the diagnosis of a suspected case of syphilotuberculosis, the following points should be borne in mind: Laryngeal phthisis is often a symptom of syphilis. Fibrous pulmonary tuberculosis should lead to a search for syphilis. In general tuberculosis is perhaps an indirect result of the inheritance of the syphilitic soil, syphilitic pneumopathies often conceal a hybrid association with tuberculosis, and the remedial effect of mercurial treatment is not alone sufficient evidence, when its influence on the soil is known, for discarding the possibility of the presence of tuberculosis. In children many diseases of tuberculous origin, especially scrofula, develop readily in syphilitic soil. Mercury is the treatment advocated by Sergent for the syphilotuberculous and he prefers it given by injections in the form of soluble salts.

Epidemiological Pseudology.

Conservative writers will be apt to deplore the tendency to see in most of the great innominate pestilences of the past nothing more than malignant influenza. The question is much more than an academic one, for the eradication of pestilence has been set down to advances in several sciences and to evolutionary progress in general. If then the innumerable deadly visitations of antiquity and the Middle Ages were very largely influenzal, we cannot be said to have advanced much, for a malady of this type can hardly be evaded or minimized when present. Cruchet in the *Journal de médecine de Bordeaux* for November 25, 1919, xc, 22, apparently takes some such viewpoint, for he criticizes his colleague Durodié for recently published beliefs that influenza makes up a very large proportion of the historical pestilences. He states that we can deduce influenza from the scanty data, but may also deduce other quite different maladies. Reading critically Thucydides' account of the plague of Athens, he concludes that it applies equally to typhus, malignant typhoid, cholera, and smallpox, to say nothing of the bubonic plague. Thucydides speaks in the same breath of "violent cough and lesions of the genitals." Why not explain these symptoms by pneumonia and inguinal buboes and call the disease bubonic plague? The plague of Athens was in part characterized by "ulcers and small pustules of the skin" but even with the plethora of symptoms in influenza, we do not find accounts of such lesions. The same is true of the mutilating affections which destroyed the limbs, and the frequent loss of sight. The first named apparently means gangrene of obscure nature while loss of sight suggests smallpox or meningitis. Moreover, there is such a thing as acquired racial immunity to certain epidemic affections. Measles and scarlatina, to go no further, must once have been deadly on a large scale, while this is perhaps true of epidemic meningitis, which has in no whit abated its deadliness today. Anthrax has recently been recognized by competent authorities as a destructive racial malady "with a past," to which man may have become largely immune through the ages.

Migraine and Anaphylaxis.

The obstinacy to treatment of migraine should be proverbial and a lifelong student of pain and its relief once made the statement that nothing but a near toxic dose of opium could neutralize an attack and then only when given very early, before the latter had become established. However, it is conceivable that once the nature of a process becomes understood, the same may yield to a remedy anything but formidable. This is well seen in syphilitic headaches and other algias, when, after defying all anodyne remedies, they promptly yield to potassium iodide. According to Pagniez, Pasteur, Valery-Radot, and Nast in an article quoted in the *Journal de médecine et de chirurgie pratiques* (October 10, 1919, xc, 19) migraine is to a large extent an anaphylactic phenomenon, and when this factor is specially in evidence the prophylactic treatment based on combating anaphylaxis is efficacious. The subject merely ingests, three-quarter of an hour before each meal, half a gram of foreign protein in the form of peptone—any good peptone will answer. The individual access will not be jugulated at the outset, but if the treatment is pursued the attacks cease to appear as long as the patient is under the influence of the remedy. The gastric symptoms yield with the headache. The same treatment has also prevailed against urticaria in a recurrent form. The conquest of migraine by peptone is naturally regarded as proof of its anaphylactic nature but this, while extremely probable, will not be straightway accepted without further evidence.

News of the Week.

Typhus Again Epidemic in Serbia. — Commissioner William J. Doherty, of the Serbian Relief Committee of America, who returned to this country recently, reports that several cases of typhus fever have developed in the hospital equipped by the committee at its headquarters at Chachack. Appalling mortality can be averted only by immediate and drastic measures for distributing medicine, doctors, nurses and supplies. Commissioner Doherty returned to this country for the purpose of obtaining money for Serbian relief work.

The Nation's Health.—The following figures regarding the health of this nation were given recently at a meeting of the American Public Health Association as an argument in favor of a National Department of Public Health: Of the 110,000,000 citizens of this country, 45,000,000 are physically imperfect; 15,000,000 die annually; 3,000,000 are in bed all the time; 1,000,000 have tuberculosis, and from 2,000,000 to 3,000,000 have hookworm and malaria. Only 37,500,000 are fairly healthy and 19,500,000 in full vigor.

Plans for Jamaica Hospital Accepted.—Plans for the two-hundred bed annex to Mary Immaculate Hospital, Jamaica, L. I., have been accepted by the Building Department of Queens. The new buildings will be memorials to the boys who served and died in the World War.

Sage Properties to be Auctioned.—The properties constituting the residuary estate of the late Mrs. Olivia Slocum Sage, widow of Russell Sage, are to be sold at auction on January 20, 1920. According to the terms of Mrs. Sage's will, the entire residuary estate will be divided among thirty-six institutions. The Presbyterian Hospital, New York City, and the New York Infirmary for Women and Children are among the number.

Falling Birth Rate of Middle Classes in England.—According to figures published by the London *Times* recently, the outlook for the perpetuation of the nation, especially the middle classes of the population, is rather gloomy. The birth date per 1,000 living at all ages, was 34.1 for 1851-60; 35.2 for 1861-70; 35.4 for 1871-80; 32.4 for 1881-90; 29.9 for 1891-1900; 27.2 for 1901-10, and 17.7 for 1918. During the period covered (1851-1910) the death rate fell by 30 per cent., it is true, but a large proportion of the fall is to be ascribed to the reduction of the infant death rate and to measures of public hygiene. Thus, as the *Times* points out, falling birth rate has been compensated for by falling death rate among the working and industrial classes. This does not apply, however, to the middle classes, whose birth rate is falling rapidly, while their death rate, never very high, is not falling and cannot fall rapidly. From these figures the *Times* holds that we are witnessing what can be described "without exaggeration as the death of the middle classes."

Year 1919 Holds Banner for Health.—New York City made its best record for healthy in the fifty-three years of the history of the Board of Health, according to the recent announcement of Dr. Royal S. Copeland, Commissioner of Health. The death rate, which was the lowest ever recorded since the department was organized, was 12.39 per one thousand of the population. In 1918 the rate was 16.71 and for the five-year period, 1913 to 1917, inclusive, it was 13.94. In other words, in 1919 there were 74,433 deaths, as against 98,119 in 1918, and an average of 83,760 for the five years, 1913 to 1917. These figures are corrected in accordance with the increase in the population. Excluding the deaths from influenza in 1918, in order to arrive at figures for comparison, the year just ended shows a decrease of 9,327 deaths. There were 176 deaths from alcoholism, 155 of which occurred during the first six months of the year, as against 48 for the last six months. There were 130,377 births reported during the year, a decrease of 9,454, as compared with the year 1918. This is one of the effects of the war, the birth rate being the lowest that we have had in the city during the last twenty years. On the other hand, the marriages increased from 56,735 in 1918 to 58,983 in 1919.

The Brooklyn Diagnostic Institute.—A welcome and hopeful sign of progress in medicine is the establishment of special hospitals and clinics for the purpose of diagnosis. A recently founded institution of this class and one that promises to enjoy a wide field of usefulness is the Brooklyn Diagnostic Institute, established at 867 St. Mark's Avenue. The aim of this clinic is declared to be "to hold at the command of the general practitioner the highest type of diagnostic skill and to be scrupulously observant of the loftiest standards of professional ethics." Dr. Jacob Gutman is director-in-chief and head of the departments of medicine and endocrinology. Each of the seventeen departments is under the direction of a well-known specialist in the given field.

Smallpox on Steamer.—Two steerage passengers arriving at New York Quarantine station January 3 were reported as having smallpox. The two patients, a man and his little daughter, were removed to Swinburne Island. The remaining 1,342 steerage passengers were sent to Hoffman Island to be vaccinated and held for observation for fourteen days. The 28 saloon and 126 second-cabin passengers and the crew were examined and those not recently vaccinated were vaccinated before being allowed to go ashore.

Object to Word "Charity."—The Norristown (Pa.) Hospital will probably have a new name after the hospital association meets, early in January, as the members object to the word "Charity" in the name which the founders gave to the institution.

Smallpox in New Jersey.—Four cases of smallpox have been admitted recently to the Essex County (N. J.) Isolation Hospital. Two of the cases, those of a mother and her son, were traced by the health authorities to Canada. It has not been ascertained how and where the disease was contracted by the other two patients.

Yellow Fever in Mexico.—Reports from Tampico, Mexico, state that an epidemic of yellow fever is raging in many cities and towns of the States of Yucatan, Campeche, Chiapas, and Oaxaca. Vera Cruz is said to be free. Quarantine has been established against several ports, including Saline Cruz, Progresa, and Frontera.

Paris Births and Deaths.—The birth rate in Paris for January, 1919, was 9.5 per thousand,

while for December of the same year it exceeded 18 per thousand. Deaths in January were 18 per thousand and in December 14 per thousand.

Barony for British Physician.—On the New Year's Day honor list in Great Britain appears the name of Sir Bertrand Dawson, physician extraordinary to King George, who was made a baron.

Otisville Hospital to be Destroyed.—United States General Hospital No. 8, at Otisville, N. Y., is to be wrecked by fire under the supervision of Dr. Royal S. Copeland, Commissioner of Health of New York City. The hospital, which was built at a cost of more than $1,000,000, was used until recently for the care of tuberculous patients. It was erected on land owned by New York City near a municipal sanitarium, and its destruction by fire is understood to be contemplated as a precautionary measure.

New System of Health Administration in Ohio.—Beginning with the new year, Ohio inaugurates a new system of local health administration, replacing that which has prevailed for more than twenty-five years. Instead of more than 2,100 city, village and township health units, the state will have 168 city and general health districts. Each of the 80 cities will be a city health district, and the territory in each county outside the cities will be a general health district. The new health administrative system was created by the Griswold amendments to the Hughes Act.

Compensation for War Cripples Increased.—The Sweet bill, increasing the compensation of disabled former service men and enlarging the classes of beneficiaries under the War Risk Insurance Act, was signed by President Wilson December 24. This bill, which practically doubles the compensation for some classes of disability, was strongly urged by the American Legion.

Health Centers for Greater New York.—It is proposed by the United Neighborhood Houses, representing forty-five settlements of Greater New York, to establish a health center in each community in which there is a settlement house. The work of these centers is to be divided into four groups, social hygiene, nutrition, tuberculosis, and maternity protection.

"Healers" Ask Recognition by Board of Education.—A large delegation of Christian Scientists appeared before the Board of Education of New York City on December 22, asking that in the cases of teachers of that faith the certificates of its medical practitioners be accepted as to their absence from school on account of illness. These practitioners, according to the plea, are registered by the Christian Science Church in Boston, hence their certificates should have the same weight as that of a regular physician. The presiding officer promised that the Board of Education would give the request of the Christian Scienists full consideration.

More Rockefeller Millions to Medicine.—According to Christmas Day announcements, the fund for medical research throughout the world was increased by $50,000,000 through the further generosity of John D. Rockefeller. This sum was placed under the control of the Rockefeller Foundation, with the special request by Mr. Rockefeller that a part of this gift be used in promoting medical education in Canada. In accordance with this request Dr. George E. Vincent, President of the Foundation, announced that the Trustees will be asked to set aside approximately $5,000,000 for the improvement and development of the leading medical schools of the Dominion. The work of building and equipping medical schools in China, and the prosecution of various other lines of medical research and education will be continued.

Deaths in New Jersey.—According to a report of the Bureau of Vital Statistics of the State Health Department of New Jersey, issued December 27, there were 2,863 deaths in that state during the month of October. Among the deaths were 402 among children under one year, 194 among children over one year and under five years, and 1,078 among persons sixty years old or over. There were twenty deaths from influenza and twenty suicides.

Influenza Epidemic in Japan.—From press notices it is learned that an epidemic of influenza similar to that of last year has developed in Japan. The Japanese Government has taken measures to check the epidemic.

Plague in South America.—According to press notices from Buenos Aires, an epidemic of bubonic plague has gained grave proportions at Las Rosas, Santa Fe Province. The National Department of Hygiene has begun a war on the rats infesting grain warehouses.

Plague at Constantinople.—The International Red Cross has confirmed reports of an outbreak of bubonic plague at Constantinople. The disease was spreading in the poorer districts of the Turkish capital, and had invaded the European quarters.

November Death Rate Low in New York City.—Dr. William Guilfoy, registrar of records of the Health Department, has announced that the city's mortality for the month of November, 9.84 per 1,000, was the lowest recorded for any month in the history of the Department. It is noteworthy that the number of deaths from tuberculosis, which usually heads the list, fell below that of cancer. There were 448 deaths due to tuberculosis and 453 due to cancer.

Special Classes for Pupils with Cardiac Derangements.—The Board of Education of New York City is to be asked to consider providing special classes for children suffering from weakness or other cardiac disturbances. Similar classes have been held during the past two years by the Educational Alliance, East Broadway and Jefferson Street, assisted by the social service of Beth Israel Hospital, and three additional classes have been organized in Manhattan and Brooklyn. Results are said to be gratifying, as shown in improvement in health and increase in weight of the pupils.

Doctors Criticised by Court.—In a recent suit for damages for alleged injury of the plaintiff by the defendant's automobile, the two physicians who attended the plaintiff, and who testified in court against him in favor of the defendant were severely criticised by Justice Guy for unethical conduct. Holding that "such utter disregard of the ethics of the medical and legal professions cannot be passed by without serious condemna-

tion." The Justice said the Bar association and medical societies should consider the case and take action.

State Hospital Commission Meets.—The State Hospital Commission and the superintendents and managers of thirteen hospitals for the insane located in different parts of New York State held their annual conference at Ward's Island December 16. A resolution was adopted indorsing Governor Smith's efforts "for the general betterment of the State hospital service as regards the employment of more labor, the payment of higher wages, the enlarging of the hospital capacity so as to do away with overcrowding, and the enlisting of the sympathy and aid of a hitherto apathetic public opinion in the service of the State toward obtaining necessary legislation in the coming session of the Legislature for suitable appropriations to carry out those ideas."

Vaccination in Madrid.—Preventive vaccination against smallpox and typhoid fever has been ordered by the Civil Governor of Madrid for every inhabitant of the city.

Plans for New Hospital Buildings.—Plans are under way for the construction of a new home for the Baptist Hospital of Columbia, S. C., to cost $300,000.

Child Welfare Key to Solution of Problem of Americanization. — In an address recently delivered in San Francisco at a child welfare luncheon arranged by the Associated Charities, Mr. Herbert Hoover expressed the belief that the entire problem of Americanization would be met in twenty years if this nation could insure proper conditions of birth, education, and nutrition.

Sir Thomas R. Fraser, ex-president of the Royal College of Physicians of Edinburgh, died January 4. He was born in Calcutta February 5, 1841. After receiving the degree of Doctor of Medicine from the University of Edinburgh, he practised for a time, but later became consulting physician for a number of medical associations and the Royal Commissioners. In 1877 he became Professor of Materia Medica in the University of Edinburgh, a position which he continued to hold until his death. From 1900 to 1902 he was President of the Royal College of Physicians of Edinburgh.

Obituary Notes.—Dr. ROBERT M. FULLER, of Schenectady, N. Y., died December 28, at the age of 75. He was graduated from the Albany Medical College in 1865, and served as surgeon in the civil war. Dr. Fuller is credited with having originated the tablet form of therapeutic preparations.

Dr. CHARLES W. PILLSBURY, of Saco, Me., died December 4, in his sixty-ninth year. He was graduated from Dartmouth Medical School in 1881.

Dr. ROBERT LEE RANDOLPH, of Baltimore, died December 11, at the age of 59. Dr. Randolph was graduated from the Medical Department of the University of Maryland, in 1884. He was attending surgeon at the Presbyterian Eye and Ear Hospital in Baltimore from 1887 to 1892, when he became associated with Johns Hopkins University in the department of ophthalmology and otology. He was the winner of the Alverenga prize of the College of Physicians of Philadelphia in 1901, and of the Boylston prize of Harvard in 1902.

Dr. JOHN E. HAGGERTY, of New York City, died at his home December 18, at the age of 43. He was graduated from the Eclectic Medical College of New York City in 1911.

Dr. FREDERICK HALVES, a retired physician of Brooklyn, died from cardiac disease December 21, in his eightieth year. Dr. Halves was graduated from Bellevue Hospital Medical School in 1870.

Dr. WILLIAM G. POTTER, formerly a practising physician of New Bedford, Mass., died at his home in South Dartmouth, Mass., December 18, after a long illness, at the age of 55. He was graduated from New York University Medical College in 1888.

Dr. EMERY MARVEL, of Atlantic City, died in Philadelphia, January 7, as the result of surgical removal of a kidney, at the age of 51. He was graduated from the medical department of the University of Pennsylvania in the class of 1895. He was a member of the Atlantic County Medical Society, the Medical Society of the State of New Jersey, a Fellow and a Vice-president of the American Medical Association, a Fellow of the American College of Surgeons, a member of the American Association of Obstetricians and Gynecologists, and a member of the Philadelphia Pediatric Society.

Obituary.

HORATIO C. WOOD, M.D.

PHILADELPHIA, PA.

Dr. HORATIO C. WOOD died at Philadelphia on January 3 at the age of 78 years as a result of pneumonia. He was graduated from the medical department of the University of Pennsylvania in the class of 1862. He served as resident physician in the Philadelphia Hospital, and from 1872 to 1907 was neurologist to this institution. He was professor of botany in the University from 1866 to 1876, and professor of material medica, pharmacy, and therapeutics from 1876 to 1907, when he was made emeritus professor. From 1875 to 1901 he was clinical professor of nervous diseases. He was president of the College of Physicians of Philadelphia in 1902-3. He was a generous contributor to medical literature, and author of a text book on materia medica and therapeutics, and of one on nervous diseases. He was made Doctor of Laws by the University of Pennsylvania, and also by Yale University.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, Dec. 19, 1919.

The Causation of Rickets.—In continental Europe rickets is termed the "English disease" because it is preponderantly in England that it flourishes. Indeed, in Great Britain it is one of the most important of children's diseases. A great deal of attention has been paid recently to its causation. In Glasgow investigations seem to show that it is chiefly due to unsanitary, badly ventilated houses and that diet is not the essential factor in its causation as it had generally been supposed. In England, on the other hand,

the majority of those who have made a study of the subject are of the opinion that diet plays the principal rôle in bringing about the condition. In support of this theory it may be pointed out that rickets is practically unknown in the West of Ireland where ignorance, poverty, bad housing and lack of sanitation prevail. And this is the case in other countries beside Ireland, in which a similar state of affairs exists. Therefore, it would appear that defective housing and so on are not the leading causes. It must be borne in mind that the symptoms of rickets are not only confined to disease of the bones. In fact, dental caries, very common in England, is an earlier and more frequent symptom than these. An early shortage of the antirachitic vitamine signifies that the tooth enamel will not be developed properly. Recent investigations have shown that in growing animals the development can be stopped, kept back and restored by lack or supply of the dietetic factor found in milk and green leaves in particular. At the present time the Medical Health Research Committee is promoting the special study of ante-natal problems. Prominent among the members of this committee are Dr. J. W. Ballantyne, pioneer in that field, and Professor Noel Paton, of Glasgow. It has been suggested that a cause of rickets may be that some expectant mothers are not fed as they should be during pregnancy. Some force is lent to this view by the fact that many breast fed children are rickety. Witness the breast fed but rachitic Negro children who are seen by no means infrequently. The problems of maternal nutrition have been too much neglected.

Need of Maternity Hospitals in Great Britain.—Sir George Newman, in the memorandum dealing with the practice of preventive medicine which he addressed to the Ministry of Health, emphasized the need for accommodation for the institutional treatment of normal and abnormal cases of confinement. In his opinion the great centers of population are in need of two-fold provision: maternity hospital accommodation for abnormal cases, maternity home accommodations for normal cases which cannot be normally or even safely dealt with in overcrowded, unsanitary or unsuitable tenements. Relatively speaking, the need for similar provision in rural districts is equally great. Many rural districts are wholly without such accommodation and in others it is inadequate. According to Sir George, what is required is, say, not less than one maternity bed per 2,000 of the population, possibly attached to or associated with the local hospital or headquarters of the district nurses. There should be a small general ward, an isolation or observation ward, a confinement ward, and where possible single wards for patients able to pay larger fees. A competent midwife-matron should be in charge.

The Teaching of Obstetrics and Gynecology to Medical Students.—A meeting of the section of the Royal Society of Medicine was held on Dec. 4 to discuss the report issued recently on the teaching of obstetrics and gynecology to medical students and graduates in London. The two points on which discussion centered were the necessity for providing more beds for lying-in women in London and the country generally, and the need for improving the facilities for teaching practical midwifery to medical students. As has just been referred to in the account of Sir George Newman's proposals, the number of beds for confinement cases in the British large centers of population is notoriously inadequate. The discussion at the Royal Society of Medicine only dealt with the maternity accommodation in London. But London may be taken as an example of the situation in this respect of all the large British cities, and London is almost without adequate accommodation for lying-in women. As the *Lancet* remarks editorially: "It is an astonishing thing that in London, the largest and wealthiest city in the world, the hospital accommodation for lying-in women should be totally inadequate; and indeed there is no lying-in hospital in London to be compared either in size or equipment with many of those to be found in quite small cities abroad or in the United States." With regard to the medical teaching of obstetrics, that question is, of course, interwoven with the establishment of maternity hospitals. If the number of these institutions is totally inadequate, then the means for teaching medical students obstetrics will also be wholly insufficient. And more than this, not only must maternity institutions be very largely increased, but in order to provide ample facilities for teaching they must be of considerable size. There may be in London two or three hospitals with medical schools attached large enough to have maternity wards with a sufficient number of beds. On the whole, however, it appears to be the opinion of many of the London medical profession that the best scheme is to establish several large midwifery institutions in different parts of London at which the students from the various hospitals may obtain their clinical instruction. While the report formulated by the Ministry of Health contains some features to be commended, it is open to criticism on many counts. In the evolution and development of so important a scheme, it is well that it should be subjected to thorough criticism by the teachers of midwifery. It is in this way that plans are perfected.

Industrial Poisoning.—In the annual report of the Chief Inspector of Factories and Workshops for 1918, issued recently, the chapter dealing with industrial poisoning, written and compiled by Dr. Legge, is of particular interest. It is pointed out that while in some industries, owing to the shortage of raw materials and the reduction of the number of persons employed, there was a large decrease in the number of poisoning cases reported; in others, the use of chemicals in the manufacture of munitions on the large scale necessary to meet the needs of the fighting forces gave rise to sudden and unexpected outbreaks of illness in the early stages of the war. Two instances are especially noticeable. In the manufacture of aeroplanes tetrachlorethane was used as an ingredient of the varnish or dope for covering the wings.

Before the beginning of the war the small and intermittent use of this substance had not been sufficient to direct attention to its injurious effects,

but toward the end of 1914, when the manufacture of aircraft had greatly developed, mysterious outbreaks of illness appeared among the workers in the doping rooms throughout the country. The symptoms, of which jaundice was a prominent one, were remarkably uniform. Investigations made by the medical inspectors found that exhaust ventilation was the most efficient means of preventing ill effects, and a ventilating plant was provided in all the doping rooms with most satisfactory results. In the meantime attention was directed to discovering a less injurious substance for the varnish. Various acetone substitutes were tried, some of them with marked success, and the use of tetrachlorethane was eventually discontinued.

The second instance was due to the use of trinitrotoluene, commonly known as T. N. T., in the manufacture of explosives. Before the war this substance was regarded as non-poisonous, and it was only its use on a large scale, and its constant manipulation by workers that directed attention to its injurious effects. Jaundice was again noticed to be one of its most serious symptoms, and in order that all possible information should be obtained, toxic jaundice was made notifiable under the Factory Act. The dust and fumes given off, especially in manipulation of the manufactured substance, were found to be the chief cause of illness, and that the measures taken to deal with the trouble were effective is shown by the striking reduction in the number of cases of toxic jaundice, which from a total of 190 in 1917, fell to only 34 in 1918.

Progress of Medical Science.

2. Primary Sarcoma of the Stomach. Review of the Case Six Years After Operation. A. R. Kimpton.
3. Functional Heart Disturbances in Women. Florence L. Meredith.
4. Enlarged Thymus Gland in Infancy and Its Treatment by Radium. Howard W. Brayton and Arthur C. Heublein.

4. Enlarged Thymus Gland in Infancy and Its Treatment by Radium.—Brayton and Heublein base this report on an experience of thirty-four cases of enlarged thymus treated with radium. In every instance there followed a prompt and lasting disappearance of all symptoms. The technique of the treatment is as follows: 100 milligrame of radium element, still in its 0.3 millimeter silver capsule, is wrapped in sufficient gauze so that when strapped to the chest by a strip of adhesive, it will lie a half-inch from the skin surface. Four marks are made in the form of a rectangle over the thymic area and the nurse is instructed to allow the package of radium to remain two hours over each mark. This makes a total exposure of 800 milligram-hours. From the moment a diagnosis of enlarged thymus is made the child's head should be kept in a flexed position, thus lessening the severity of the asthma and the possibility of sudden death. Radium possesses the following advantages over the Roentgen ray in the treatment of these cases: The action of radium is more rapid; with radium one treatment alone suffices to effect a cure, even in the severest forms of the disease; radium is portable, thus obviating the difficulty of transporting the patient to a Roentgen laboratory; the application of radium is simple, thus eliminating the dangerous element of fear from the mind of the patient, and at the same time rendering unnecessary the use of an elaborate *x*-ray equipment and highly skilled operator.

8. Gonococcemia and Metastatic Gonorrhea. Hyman I. Goldstein.

4. Principles of the New Method of Administering Digitalis.—Harold E. B. Pardee calls attention to the many new facts which have been brought forward during the last few years regarding the action of digitalis. The laboratory and the hospital clinic have contributed to these discoveries. A new understanding of digitalis has been reached through more accurate knowledge, and new methods of administration have resulted. Digitalis has been found to be more effective in the treatment of the patient with heart disease when his body is well saturated with the drug, than when it is present in small amounts only. The best therapeutic results are obtained when the patient is not far short of that stage of saturation at which the earliest manifestations of poisoning appear. Therefore, if one would be sure of results, one should give digitalis in fairly large doses, watching carefully for these early manifestations, and should not stop the drug until they appear. Digitalization has come to mea nthe giving of digitalis to this point of saturation. The procedure recommended by Pardee is to start with a large dose on the first day, perhaps a half of the calculated average dose, which will be one minim of the tincture to each pound of the patient's weight, and then to complete the course with smaller doses at four-hour intervals on the days following. If these smaller doses are each one-eighth of the remaining half of the calculated dose, they will vary from twelve to twenty-five minims according to the weight of the patient, and if this dose is given every four hours, then the total calculated amount, the average effective dose, will be received within a period of three days at the most. When the susceptibility of the patient is greater than the average, he may show the early toxic signs even as soon as the second day; when the susceptibility is less than the average it may be necessary to continue the four hourly doses for one to two days longer before the signs of poisoning appear. By this method of dividing the doses one is able to reach the end point rapidly, but not so rapidly that the administration cannot be stopped in time to avoid vomiting. Should it be found that with this dose one is unable to perceive the approach of the vomiting stage soon euough to stop the drug in time to avoid vomiting, or should the patient not be under daily observation, then it would be advisable to go more slowly as the point of saturation is approached. The four hourly doses should then be given only three times a day. When digitalis is to be taken in accordance with the plan outlined, the patient must not have taken any of the drug for a period of at least two weeks before beginning the treatment by this method.

1. Do Calories Measure the Value of Food?—Henry Dwight Chapin, after a reexamination of some of the foundations of the problems of nutrition, summarizes the question as follows: Heat or energy may be produced by chemical cleavage as well as by oxidation. Heat may be a degradation of energy, and in the human organism it is an excretion. Heat measurement alone is not a safe guide for the calculation of food values. This is especially true at the beginning of life when growth is the all-important factor. The foods that *build* rather than those that readily undergo oxidation must be properly gauged if we are to have healthy development. A false theory does harm in that it points in the wrong direction, and it is a question whether it is not time to weigh carefully the calory theory of feeding and restrict or partially abandon its use. To take its place, a system of teaching must be constructed based on a knowledge of the physiologic properties of the various food elements and the fact that there are mixed types of metabolism. Some form of biologic testing of foods must be elaborated if an always reliable gauge of nutrition is to be established.

6. Asynchronism of the Respiratory Movements in Lobar Pneumonia.—Warren Coleman holds that asynchronous contractions of the respiratory muscles occur in many cases of lobar pneumonia. In the fully developed type of asynchronous breathing, the diaphragm and thoracic respiratory muscles contract alternately, with the result that the abdomen and the chest "see-saw" up and down. The cause of the phenomenon probably lies in unequal depression of different parts of the central nervous respiratory mechanism. The development of asynchronous breathing usually augurs a fatal termination.

7. The Frequency of Right Inguinal Hernia after Appendicectomy by the "Gridiron" Incision.—G. H. C. St. George Griffiths collected 11 cases of inguinal hernia following appendicectomy, ten of which were on the right side and one on the left. The date of the appearance of the hernia varied from a few months to three and a half years after the appendicectomy was performed. In 10 cases the gridiron incision was used, none of the incisions being near the outer border of the right rectus. In the eleventh case a Battle's scar was present, the hernia having appeared 18 months after operation. No one can state with accuracy whether there was a predisposition to a hernial formation in each of these recorded herniæ. Such a predisposition might account for the one appearing in the left inguinal canal, and also the hernia following Battle's method. Anatomically there is no explanation for these two herniæ. This leaves nine right inguinal herniæ following appendicectomy by the gridiron incision to be accounted for. The explanation must be sought for in some fault in the technique in making or closing the gridiron incision. The writer suggests that it may occur either by avulsion of division of the fine muscular nerve twigs to the lower portions of the internal oblique and transversalis muscles during the opening of the peritoneal cavity, and leading to a partial complete atrophy of the muscle-fibres in the region of the internal abdominal ring; or, on the other hand, by compression of the same nerves by the encircling catgut sutures in sewing up the incisions in the transversalis and internal oblique muscles, in repairing the abdomen after appendicectomy. From the fact that these 11 cases appeared in a little over a hundred consecutive cases of inguinal hernia, the writer considers that a new plea for Battle's method arises, to avoid the possible occurrence of this annoying end-result to appendicectomy by the muscle-splitting incision.

4. Mumps in Adults: An Analysis of 694 Cases.—George Macleod offers as the only plea for the publication of clinical notes on what is usually regarded as a mild contagious disease of childhood the circumstance that the war has afforded opportunities for the study of its manifestations in adults. Of the 694 cases, 78 per cent. occurred among Australian troops, who offered peculiar facilities for the spread of the disease in a virgin soil, as very few of them had previously been exposed to this infection, which consequently overran entire units in a short space of time. All the cases occurred in adult males from 17 to 40 years of age. Seventeen were second attacks, and one claimed to have celebrated his third attack. The onset was characterized by the usual symptoms. The parotid glands were usually the first affected, and in 64 per cent. the left parotid was the first to be involved; in 17 per cent. the disease was confined to the left side, in 20 per cent. the right side alone was affected, while in the remainder the glands on both sides were ultimately implicated. In two cases the disease first appeared in the submaxillary glands, and spread to the parotids later. In nine cases orchitis was the first manifestation; four of these had no glandular involvement, two others had pain only in the lower jaws, and the remaining three developed parotitis three or four days after the onset of the orchitis. In several cases redness and edema or a whitish exudate was observed around the orifice of Stenson's duct, but no casual organism was recovered. Orchitis was the most frequent complication, occurring in 140, or 20 per cent. of the cases. Symptoms suggestive of pancreatitis were observed in six cases, all of whom made good recoveries. In 48 cases which, after a primary attack of ordinary severity, had already entered on convalescence, the temperature rose abruptly on the seven to tenth day to 100° or even 104° F., with a pulse rate of 80 to 120. Apart from a feeling of general malaise, there were no local manifestations to indicate the seat of this complication, which was apparently toxic in character. The temperature fell by crisis in two to five days, convalescence being uninterrupted thereafter. Other complications include bronchitis, tonsilitis, rheumatism, and conjunctivitis; laryngitis and aphonia occurred in 8 cases, earache and deafness in 3, otorrhea in 2, while in 2 cases suppuration of the parotid occurred. In 2 cases death occurred from intercurrent disease. Relapses were met with in 17 cases.

Intolerance of the Nursling Toward Milk Treated with Subcutaneous Injections of Milk.—Weill makes a follow-up communication on this subject, his first dating from December, 1918. The intolerance mentioned does not extend to that which accompanies severe infection or stenosis of the pylorus. He thinks so well of this resource that he would use it in all obstinate cases of simple intolerance. The latter is expressed by the rejection of nearly all the amount ingested. This

may be prompt or retarded. In addition the number of movements is increased over the normal and the discharge irritates the skin. To these symptoms are added disturbance of the nervous centers which lead to poor sleep, restlessness, excessive crying, etc. Naturally in these cases much can be accomplished by diet. In regard to breast milk it must not be understood that this confers any immunity, for the contrary has been shown. The author makes no statement in this connection of Czerny's exudative diathesis as a cause of this intolerance but seems inclined to attribute the latter to some maternal or infantile factor such as influence in the mother and the same in the infant along with ordinary cowpox vaccination, chicken pox or other mild constitutional disturbance including the sequelæ of a gastro-enteric infection. Intolerance may appear in the absence of all evidence pointing to the stomach itself, as in cases where the mere presence of metrorrhagia in the mother has been followed by milk intolerance. The author regards the process as a matter of anaphylaxis. Cow's milk, even in minute quantities, has caused fatal anaphylaxis in children already in the throes of cholera nostras. In addition to major anaphylaxis a minor or specific alimentary anaphylaxis must be considered. Cow's milk being foreign protein is naturally much more active in the production of anaphylactic phenomena than breast milk. To give brief histories, one baby 6 months old presented intolerance to mother's milk and cried all night. It received an injection of warm breast milk, 10 c.c. subcutaneously, and at once obtained normal sleep. In another child a positive intradermic reaction to mother's milk was first obtained. One c.c. subcutaneously then gave an intense reaction and prompt removal of all symptoms of intolerance. In other cases but a few minims were injected. The author terms the treatment a genuine "milk vaccination" which need not be repeated and gives permanent results.

Syphilis of the Stomach.—Bensaude and Rivet describe cases of all five types of gastric syphilis, to wit: syphilitic gastric ulcer, syphilitic gastric tumor or pseudo-cancer, syphilitic linitis, syphilitic gastric stenosis, and the gastric crises of tabes. In stenotic affections we see both ordinary pyloric stenosis and hour-glass stomach. The authors sum up the clinical aspects as follows: in making a diagnosis in any of these cases we depend on the history and collateral evidences of syphilis including tabes and paresis, on the Wassermann reaction, on gastric chemistry, the *x*-ray and the treatment test. It is largely a matter of excluding ordinary ulcer, cancer, perigastritis and other organic diseases of the stomach. As in other organs when the symptoms are confused and atypical, we should think of syphilis. The authors lay much stress on the treatment test carried out as follows: iodides and mercurials are given jointly by the mouth, these being as a rule well borne. Syphilis at once shows improvement while the other conditions are made worse. The stenosing forms are naturally more difficult to benefit. The improvement is manifest, not only in the local but in the general symptoms. Untreated this affection leads to cachexia and death. Surgery is of value only when the disease has produced incurable stenosis.

Suppression of Begging in Madrid.—Maranon refers to a recent visit of inspection to the beggar's camp in company with various functionaries of the province and city, with a view of ascertaining the possibility of the suppression of mendicancy. The quarters supplied to these unfortunates under the name of charity are too wretched for words and moved the author to indignation and shame. Conditions are filthy beyond description and only radical measures can be invoked to secure amelioration. The camp is a menace to the health of the city. In 1910 Madrid was attacked by typhus and it might be naturally supposed that this fact alone would prove a sufficient motive to proceed against the problem of mendicancy, but none of the subsequent governors of the city has made any move in this direction. When the police drive the beggars from the main thoroughfares, this is not a sanitary crusade. The police, however, could be made to aid in a campaign of disinfection. It is something to have the beggars rounded up but no advantage is taken of this fact to have them bathed and deloused. The habitations have no ventilation, the beggars have but scanty clothing and they receive but little food. In the past, several epidemics of typhus have been traced to them and in theory they could spread almost any kind of infection. (There is no evidence that they were in any way responsible for the outbreak of influenza in 1918, which seems to have first appeared among the early rising market men of the city.) Clearly the first step should be to save the children of the beggars, who are badly undernourished and half destitute of clothing. Other classes, as the sick and superannuated, should then be given support. The custom of herding the beggars together may have advantages, but such a state of affairs is far more dangerous from the standpoint of epidemics than the opposite condition of vagabondage. The trouble has always been a shifting of responsibility, but the time will eventually come when this problem must be settled.

Tetanus in the French Army During 1918.—Sieur and Mercier have determined the incidence of tetanus in 150,000 French soldiers wounded in 1918. The rate was 0.06 per 1000 in the army zone, 0.19 per 1000 in the intermediate zone, and 0.30 per 1000 in the zone of the interior. These results surpass those of previous years and are to be attributed to the serum treatment which had been systematized with improvements in technic. These figures concern the morbidity only, no death rates being given. The serum, therefore, prevented the development of the disease or modified it favorably.—*La Presse Médicale.*

Pharmacological Study of Finnish Digitalis.—Grönberg states that it is possible to grow medicinal digitalis in Finland if it is a question of seeds with a titer value of 4. A digitalis grown artificially will have the same worth as the best wild digitalis from Germany. The plant grows best in sandy or garden soil without any glass protection or any defense against cold and wind. Young plants, however, need abundant moisture. The leaf stems should not be included in the harvest. There appears to be no difference in merit between one-year and two-year digitalis.—*Finska Läkaresällskapets Handlingar.*

War Rations and Diabetes.—Singer, an Austrian practitioner, writing of conditions in Austria during the war, states that rationing was of marked benefit for the glycosuric and diabetic. All degrees were favorably influenced. Many patients became sugar-free and showed a relatively high carbohydrate tolerance. The blood-sugar values were relatively low. This must be ascribed to the poverty of war rations in albumin. The ration of war can become the basis of the therapy of peace.—*Correspondenz-Blatt für Schweizer Aerzte.*

Morbidity of Finland for May.—The total number of cases of notifiable disease for the month was nearly 11,000, and of this number nearly one half were due to the second wave of influenza which began in March. The first wave occupied the Fall months of 1918. There are 32 classifications of notifiable diseases. The number of cases of laryngobronchitis was over 1600 while gastroenteric acute diseases numbered 882. These figures may include masked influenza. The number of cases of gonorrhea reported was 527, of recent syphilis 180, and of ulcus molle 106.—*Finska Läkaresällskapets Handlingar.*

Deaths from Narcosis.—Desmarest, in 6000 personal cases of narcosis, has lost 2 patients from chloroform, 2 from ether, 2 from intraspinal analgesia and 1 from kelene. He is appalled at this record and in his search for a less murderous substance has followed the Americans into the field of nitrous oxide. With Amiot he first elaborated a technic with suitable apparatus and thus far in 300 anesthesias has had no untoward result. —*Le Bulletin Médical.*

Book Reviews.

AN ATLAS OF DENTAL EXTRACTION, with notes on the Causes and Relief of Dental Pain. Designed for the Use of Medical Students and Practitioners. By C. EDWARD WALLIS, M.R.C.S., L.R.C.P., L.D.S., Dental Surgeon and Lecturer on Dental Surgery Kings' College Hospital; Assistant Medical Officer (Public Health Department) London County Council; Late Dental Surgeon Victoria Hospital for Children, Chelsea, etc. Second Edition. With Eleven Plates. Philadelphia: P. Blakiston Son & Co., 1919.

IN many rural districts, remote from a large town, the medical man of the place is even yet often obliged to treat the teeth as well as the other parts of his patients. As this is usually emergency treatment, his essential duties consist in the application of such remedies as will still pain, or in the failure to do that the extraction of the offending tooth. For such emergencies this book will be of great service. The text consists of two chapters: "The Causes and Relief of Dental Pain" and "General Notes on Extraction of Teeth." The eleven plates, each double-page, depict the teeth to be extracted, the instruments required in each case, and their mode of employment. The rural practitioner, the ship's surgeon, and sometimes the industrial physician will find this book to fulfil perfectly the purpose for which it was written.

A TEXT-BOOK OF UROLOGY IN MEN, WOMEN AND CHILDREN; including Urinary and Sexual Infections, Urethroscopy and Cystoscopy. By VICTOR COX PEDERSEN, A.M., M.D., F.A.C.S. Major, Medical Corps, United States Army; Consulting Physician to the Selective Service Headquarters in the City of New York; Member of the Council of National Defence, New York State Committee, Medical Section; Visiting Urologist to St. Mark's Hospital; Major, Medical Reserve Corps, United States of America. Member of the American Urological Association, American Medical Association, New York State and County Medical Societies, New York Academy of Medicine, American Electrotherapeutic Association, The Association of Military Surgeons of the United States, and of the Committee on Venereal Diseases of the Advisory Council of the Department of Health of New York City. Illustrated with 362 engravings, of which 152 are original and 13 colored plates. Philadelphia and New York: Lea & Febiger, 1919.

THE author of this volume deserves much praise for his comprehensive review of Urology. In one thousand pages he discusses urethritis in all its forms and phases, urethral stricture, gonococcal infection in the female, various instrumental diagnostic procedures, renal functional tests and suppurative conditions of the upper urinary tract. The text is enriched with original illustrations and abounds with the spirit of fair play in according credit to other students and authors. A tendency toward lack of balance results from disparity in the consideration of important and non-important subjects. Balanitis, posthitis and like inconsequential conditions are treated with the thoroughness of an essay, whilst the reader would be grateful had the author given the same space and work to his views and advice on sexual disabilities subsequent to infections of the urologic and genital tract. Such wealth of information, unless skillfully massed, becomes unwieldy and unfortunately, the author's arrangement of his subject is confusing. General principles of diagnosis including physical and laboratory examinations are placed in the middle of the work. The subject of Cystitis is taken up in the section of complications of urethritis; again in Chapter xiv on the bladder. Much therapeutic value is claimed for electrotherapy and heliotherapy. The literary style is far from flawless perfection. Hawthorne's remark that his style was the result of his desire to tell the simple truth as honestly and vididly as possible, has gone unheeded, for Dr. Pedersen, in his desire to make his child entertaining, often strays into somewhat cloudy English. But withal this is a contribution of real worth to the literature of urology and one that will be found most helpful by every student of this specialty.

WAR NEUROSES AND SHELL SHOCK. By FREDERICK W. MOTT, M.D., LL.D., F.R.C.P.; Brevet Lt.-Col. R.A.M.C. (T.), Senior Neurologist to the Maudsley Neurological Clearing Hospital; Consulting Physician Charing Cross Hospital; Director of the Pathological Laboratory of the L. C. C. Asylums; Corresponding Member of the Neurological and Psychiatrical Societies of Paris. With a Preface by the Rt. Hon. CHRISTOPHER ADDISON, M.P., Minister of Reconstruction. Pp. 348, with three color plates and 93 illustrations in the text. London: Henry Froude, and Hodder & Stoughton; New York: Oxford University Press, American Branch, 1919.

THE author of this volume has had exceptional opportunities for first-hand study of the victim, himself, of war neurosis or shell-shock, of the clinical manifestations of these conditions, of the histopathology of the nervous system which has undergone the injury of the category under consideration, and of the results of treatment and after-treatment. The book, which consists of 328 pages of text, including the Appendix, and with 19 additional pages of index, is not divided into chapters. but the subject matter is dealt with under individual headings, of which there are more than a hundred. The volume would seem to be of special interest and usefulness, (1) to the neuropsychiatrist, because of the complete account of the pathological changes in the nervous system in shell-shock and gas poisoning, as well as the discussion of the clinical phases of these affections; (2) to the neurologist, to the family physician, to the reconstruction worker, and, through these, to the patient's family and the community at large, because of the discussion of treatment and after-treatment of the patient and his disability; (3) to the medicomilitary establishment, because of the clear demonstration of the importance, in recruiting and subsequently in assigning the individual to a category for military service, "of studying what a man is born with and what happened after birth;" and (4) to the pension department, whatever form the governmental financial after-care of the disabled soldier may assume.

It is well remembered that early in the war Mott directed attention to the importance of predisposing factors of war psychoneuroses; continued experience amply proved the correctness of this view, and fully warrants his emphasis, in this volume, of the fallacy of trying to convert men with an acquired or inborn predisposition of emotivity into good military material. From a study of one hundred cases of war psychoneuroses and one hundred cases of somatic injuries produced in the firing-line, Mott found that cases of war neurosis were very rarely associated with external or somatic wounds. The vast majority of the psychoneurotic cases were among soldiers who had a neuropathic or psychopathic soil. In 74 per cent of these cases a family history of neurotic or psychotic stigmata, including insanity, epilepsy, alcoholism, and nervousness, was obtained, while a previous neuropathic constitution in the patient himself was present in 72 per cent. A gradual psychic shock from long-continued fear, together with the sudden change from quiet, peaceful environment to the extraordinary stress and strain of trench fighting, is assigned as the chief predisposing cause of war psychoneurosis in soldiers with this neuropathic predisposition. Indeed, these factors may be the cause of the neurosis *per se*. The significance of these and many similar findings is emphasized, and illustrative cases are described and illustrated.

The subject of treatment falls under the prevention of gas poisoning and accidents in mines; the treatment of carbon monoxide poisoning; the general treatment of shell-shock and neurasthenia; mental hygiene in later stages; the treatment of hysterical paralyses, contracture, mutism and other disabilities; the atmosphere of cure; exercises for convalescent cases of war neurosis; the treatment of hysterical sensory conditions; physiopsychotherapy in the treatment of mutism; the treatment of stammering and stuttering; physiopsychotherapy in the treatment of paralysis and analgesia; the gymnasium in the treatment after functional paralysis and contractures; and after-treatment by occupation.

Society Reports.

THE AMERICAN PEDIATRIC SOCIETY.

Thirty-first Annual Meeting, Held in Atlantic City, N. J., June 16, 17, and 18, 1919.

THE PRESIDENT, DR. EDWIN E. GRAHAM, IN THE CHAIR.

(*Concluded from page 37.*)

The Cause of a Sporadic Case of Cerebrospinal Meningitis—Dr. HENRY L. K. SHAW of Albany reported this case, which developed in an infant five months old, breast-fed, and living on a farm. All who came to the house during the previous week could be found and examined because of the isolated position of the farm; no former cases were recorded in this place. The baby had been fondled on January 28 by an enlisted man who had been to France and had returned that month, being discharged from Camp Upton on the 27th. The baby was taken ill in a few days. The soldier claimed that as far as he knew he had never seen, been in contact with, or heard of a case of meningitis in his regiment, but he was found to be a meningococcus carrier. All other visitors to the farm gave negative nasal cultures. The meningococci obtained from the soldier were agglutinated by the fluid from the spine of the baby and were also proven identical by cultural growth. The organisms still remained on this carrier on June 10, which was an interesting fact. All attempts to rid the soldier of the meningococci by irrigations of all kinds under a nose and throat specialist failed, and his condition was pitiable—he could not return to the army; though in perfect health, he was in quarantine, thus being unable to support himself or his family, and the War Risk Insurance Bureau, Public Health Service, and Red Cross all claimed they had neither funds nor authority to reimburse him. Discussing so-called sporadic cases and those which had apparently been traced to fomites, Dr. Shaw expressed the opinion that such cases could always be traced back to a previous case if full facts were obtained. Failure to comprehend modes of infection, both by the laity and the medical profession, was the cause why full facts were not obtained. That persons, not things, were the cause for the transmission of communicable disease was difficult to bring before the public and even those of the medical profession. In many cases alleged fomites infection was really carrier infection. It was much more likely that persons on whom the germs were growing were the agents of infection than objects on which the germs were dying. Many observers agreed that the transmission of disease through the air and by fomites had been disproven, and that the present explanation of communication was by infected persons, unrecognized cases, and healthy carriers. Epidemiologists claimed that after a communicable disease had become established and carriers numerous, isolation and quarantine were of little avail. Contagious disease could be checked by prompt and strict isolation and an early and diligent hunt for carriers. In the case above they had cut off all chance for development by detecting the carrier and by isolation. Had this carrier lived in a city and had he had a number of nieces, nephews, and admirers, it would have meant a wider distribution of cases and a large number of carriers. Then isolation, quarantine, and disinfection would not have controlled the situation. As the disposition of carriers was largely a public health measure, a questionnaire was sent to the various State departments of health in order to ascertain their mode of procedure regarding carriers of meningitis. The answers quoted showed little uniformity in isolation and in dealing with carriers. There was nothing for the detection of healthy carriers and the compulsory bacteriological examination of contacts. To limit the spread of communicable disease public health legislation was imperative. The duty of pediatricians was to keep abreast of public health progress and assist in educating our communities to the new order of things. From the study of this case the writer felt right in claiming that it was caused by contact with a healthy passive carrier, that sporadic cases were in reality untraced cases, and that the human carrier was the cause for cases appearing either singly or in epidemics.

Dr. FRITZ B. TALBOT of Boston said that this paper was very important and timely, as it served to bring out the susceptibility of the young to infectious diseases. It was the practice in the armies in Europe when they found a carrier to send him to a camp where there was below a certain number of carriers and in that way they diluted the infection, and if the infection was sufficiently diluted no epidemic occurred. He thought Dr. Shaw's case was suggestive of what would happen in civil life if that plan were adopted.

Dr. L. EMMETT HOLT cited a case which paralleled that reported by Dr. Shaw. He urged the importance of recognizing that many thousands of returning soldiers were distributed through the community and that undoubtedly a number of them were carriers of disease and as a consequence they would be likely to see many of these cases cropping up.

Dr. HENRY KOPLIK discussed the many difficulties that presented themselves in connection with the problem of dealing with carriers. He expressed the opinion that it would be impossible to care for all carriers. He also cited another case somewhat similar to Dr. Shaw's.

Dr. HENRY HEIMAN of New York related the case of an infant six weeks old that contracted meningitis though it had never been out of the house and was in charge of a nurse. They had made it a practice to take two nose and throat cultures of all those who had come into contact with a case of meningococcus meningitis in order to label the carriers, but they had found that they could not do much for them, as it was extremely difficult to get rid of the organisms. They were now beginning to see cases of trench mouth, an infection that was being brought home by the soldiers.

Cerebrospinal Involvement in Hereditary Syphilis.—Dr. P. C. JEANS of St. Louis presented this paper, in which he stated that evidence showed that about 30 per cent. of syphilitic infants had changes in the cerebrospinal fluid of such a character and degree as to make the diagnosis of syphilitic involvement of the nervous system seem quite certain. There might or might not be associated clinical manifestations indicating neurosyphilis. Intravenous and intramuscular treatment would result in most instances in the disappearance of the abnormal findings both in the cerebrospinal fluid and in the blood. Similarly, routine spinal puncture in older children having either latent or active syphilis showed evidence of neurosyphilis in about 30 per cent. of those examined. Clinical signs of neurosyphilis might be present or absent. Prolonged intravenous or intramuscular treatment would eventually result in a negative blood Wassermann, while the cerebrospinal fluid might or might not continue to show changes indicating neurosyphilis. Intraspinal treatment would cause the disappearance of pathological changes in the spinal fluid when these had persisted. Justice to their syphilitic patients demanded that the state of the nervous system, as indicated by the cerebrospinal fluid, be known in each case. Great injustice was done when the patient was discharged after being treated to clinical recovery and negative blood reaction without knowing the condition of the central nervous system as shown by the cerebrospinal fluid.

Dr. W. MCKIM MARRIOTT of St. Louis pointed out that these studies were of more than academic interest as they had a direct bearing on prognosis and treatment. Dr. Jeans had made careful observations on the spinal fluid after the administration of arsenic when mercury had not been given first. He found that the administration of arsenic before mercury was given might result in the serious Herxheimer reaction. A further practical application of Dr. Jeans', work was that if they watched the spinal fluid in cases that were apparently cured, after being treated in the usual way and after the blood had become negative as shown by the Wassermann test, the cerebrospinal fluid might still be positive.

Dr. L. R. DEBUYS of New Orleans stated that one should not be too ready to exclude syphilis in the presence of a negative blood Wassermann. The cerebrospinal fluid should be examined in every case in which congenital lues was suspected.

A Health Study in a Boys' School.—Dr. RICHARD M. SMITH of Boston read this paper, in which he reviewed the work done thus far in the care of school children regarding the detection and correction of physical defects and the provision of proper food for the undernourished. He stated that many schools used his plan entirely, and that all schools used some part of it. Very few schools had studied the health of the children regarding all the factors in the child's life and their interrelation. In this matter the public schools were ahead of the private schools; and some private schools had entirely neglected the question of health. As pediatrists, chiefly responsible for the health of school children, there were certain matters to be definitely acted upon and certain minimum standards of health supervision to which every school child was entitled. These were: (1) Every school child should have a complete physical examination at least once a year and corrective measures should be taken for defects and diseases. The children should be watched that no defects or diseases developed while in school. In refutation of the statement that it was impossible to undress children for examination, he felt that parents would not object if they understood that it was necessary for a satisfactory examination. (2) As school nurses were really health instructors, proper qualifications in efficiency should be insisted upon. (3) Better understanding and closer cooperation should come between school authorities, the family physician, and the dentist. Unity of action must be had for the child's health. If minimum standards for school children were established and taught there would be no conflict of advice. This involved the introduction of the teaching of school hygiene in the medical schools, a development which was sure to come in time and which they should try to secure at once. (4) They should not confine their attention simply to those with malnutrition, but should look to the good of all, and to this end, that all might be kept in good nutritional order, good school lunches should be served and correct supervision be given to the method of eating. In viewing the future extension of health supervision there were additional features to be attended to. These were: (1) There must be a general recognition of the importance of good health. Draft records showed that our present health methods did not yield satisfactory results. Health was necessary for progress. (2) School authorities, both public and private, must see that health was considered as important as scholarship, and that health did not pay for education. (3) There was the need of cooperation from parents in protecting the health of their children. Parents were careless about planning activities for their children outside of school hours; activities should be planned in connection with school work. School master, parent, those interested in child welfare, and the physician must act together to see that the child's life as a whole was lived to protect his health. (4) It was important that the pupils themselves should receive instruction regarding health. The teaching of health to pupils must eventually be in the hands of school authorities. This could be only when the school authorities recognized the importance of health and after they had received from physicians information as to the proper things to teach. This made it necessary for them to be ready to submit courses of instruction for teaching health to children. Dr. Smith then described the methods used in Mr. Rivers' Open Air School for Boys, established in Boston in 1915. There was in connection with his school an advisory medical committee to whom the details of the curriculum were submitted in order that education and health might be considered in relation to each other. The work of the school was conducted in open air classrooms. The food was approved by the medical advisory committee. The children had rest periods each day as a definite part of the curriculum, and adapatd to the varying needs of the boy at different ages. Each boy's program was explained in detail to his parents and the importance of planning his home time in relation to this program. The school sent the boy to his family physician for advice when the progress in school or the health of the boy was suffering from a physical condition needing correction. There was a school matron whose sole duty was to look after the health of the children, under the supervision of the head of the school and the medical advisory committee. The complete application of the program required the cooperation of the parents. From the writer's experience in the study of boys in school over a period of several years he had arrived at standard percentages to be given to study, inactivity, and activity, at different ages from six to fifteen years. Charts were presented showing that illness was usually the reason for absence from school. Other charts showed the progress of undernourished children under careful supervision, both as to their improved physical condition and their progress in scholarship.

Dr. FRITZ B. TALBOT of Boston said he considered Dr. Smith's paper very important because he had had an experimental laboratory in which to try out what physicians thought should be done in schools, and so far as he knew it was the first time that everything had been done as the physician wished. The tendency among educational authorities to maintain all the features of a health program without the advice of a physician was to be deplored. The paper, while emphasizing the importance of undernutrition, made it plain that the basis of the study of nutrition was not sound. This Dr. Holt had pointed out when he made his study of the weights and heights of boys in a private school. The great difficulty they had encountered in their nutritional studies was that of determining the standards for the normal child. This was the most important point to settle.

Dr. SAMUEL MCC. HAMILL of Philadelphia, after congratulating Dr. Smith on being the first to emphasize the need of medical supervision in a boys' boarding school, said he had had the opportunity of coming into contact with boarding schools and was astonished at the neglect of medical supervision. He placed emphasis on the point that it was not only the undernourished boy who needed attention, but that the boy who was consuming an amount of food that he was utterly unable to take care of was just as greatly in need of attention. The boys' school offered an opportunity to make some observation with reference to what constituted a normal food intake for boys of school age in twenty-four hours.

Dr. THOMAS S. SOUTHWORTH of New York emphasized the advantages of an extension of school medical supervision in an advisory capacity to the home. He cited the case of a boy overworked by extra studies and instructive holiday excursions so that he was left no time for mental recuperation in order to illustrate the effect on the child of undue forcing and to show the need for closer cooperation between the home and the school.

Dr. L. E. LA FETRA expressed his approval of the plan of having regular periods of activity and inactivity for the boys. He said that perhaps Dr. Smith had not sufficiently emphasized the advantages of having periods of rest between study periods. Efficiency engineers had found that by the introduction of short rest periods of five or ten minutes every forty-five or fifty minutes, the degree of fatigue, the number of absences, and the labor turnover were greatly decreased. The same principle should be applied to the growing child. Another factor of importance, not so much in private as in public schools, was that the lunch period was too short. The lunch period should be long enough to permit the child to eat his lunch in comfort and to allow him a period of repose before going back to school.

Dr. ISAAC ABT of Chicago said that if teachers knew more about health and doctors knew more about education better results would be obtained. Too many doctors went into the work of school inspection unprepared. The matter of school inspection had a brilliant future, but at present it was a failure. Medical inspection in the schools should be left to the best men in the community and not to the young men who knew little or nothing about it.

Dr. HENRY F. HELMHOLZ of Chicago spoke of the responsibility of the society from the standpoint of preventive medicine. As pediatrists, he said, they had strangely neglected this phase of their work. They should devote more attention to preventive medicine. Once every year or every second year they should devote a session to the discussion of some phase of preventive medicine as it related to pediatrics.

Dr. HENRY L. K. SHAW of Albany emphasized a number of the points brought out in the discussion and agreed with Dr. Abt that one of the reasons medical inspection of the schools was a failure to a certain degree was due to their lack of knowledge and their indifference to the subject. He made a plea for better training in pediatrics and public health work in our medical schools. During the last few years the term "medical school inspection" had been superseded by the more desirable term "medical school health supervision."

Dr. L. EMMETT HOLT of New York said that they all realized the situation, but the question was "What was the remedy?" The public could only be awakened to a realization of the situation by the education of public opinion, and that was what this society should make an effort to do.

Dr. HENRY HEIMAN of New York advocated an extension of health supervision such as Dr. Smith had described to the summer camps for children.

The Predominance of Seborrheic Eczema in Early Life.—Dr. THOMAS S. SOUTHWORTH of New York presented this communication. He referred to the recent trend of pediatric literature which considered the majority of infantile eczemas to be due to dietetic or other internal causes. He did not wish in any way to detract from the value of that work; both from the etiological and therapeutical standpoints he acknowledged its value. Nevertheless, it appeared that the part played by seborrhea had been overlooked and had failed to receive the recognition it deserved. His observation had been that a preponderance of the cases of eczema presenting themselves in the ordinary routine of pediatric practice were associated with seborrhea, many of which were so mild that they would never reach the dermatological specialist. The writer had traced the seborrheic factor in both the mild and severe types of eczema. The clue to such basic causation was found about the ears and upon the scalp. The ear signs in seborrhea might vary from a mere adherent dry exfoliation to a moist and exuding surface where two surfaces were in contact. There was something significent also in the predilection of such eczemas for fat babies on breast milk rich in fats and for bottle babies suffering from disturbed digestion caused by a relatively excessive intake of fat. Towle and Talbot, in their description of cases of eczema associated with faulty digestion of fat, had noted the tendency of the exudative eruption to remain limited to the regions of the head for an appreciable length of time. There seemed to be some local predisposition. In nearly every case of marked facial eczema some characteristic lesion would be found, if sought for, above or below the ear. No attention had hitherto been called to this association, and it had generally been overlooked. The acceptance of a seborrheic predisposition appeared also to afford an explanation of the fact that facial eczemas tended to involve the hairy scalp rather than the neck and chest. The recognition of a seborrheic basis for a lesion by no means excluded the possibility of other microscopic invasion. As to treatment, oxide of zinc ointment, so helpful in other types, was, as a rule, useless by itself in seborrheic cases of even the simplest form. The soothing bland ointments, in the writer's experience, were unavailing until to them were added ammoniated mercury or tar, or resorcin, to destroy the microorganisms present. The part played by diet, both in the causation and cure of facial eczemas of infancy, was recognized by all, and this dietetic factor must be differentiated and corrected before the larger number of cases would yield to treatment.

Aneurysm of the Ascending Arch of the Aorta in a Boy of Thirteen Years.—Dr. HENRY HEIMAN of New York reported this case. He stated that the boy's illness began eight years ago with the gradual onset of dyspnea on exertion, precordial pain, and a slight cough. He gave a history of having had several attacks of articular rheumatism. In addition to physical signs, the electrocardiogram showed marked left ventricular preponderance, and the fluoroscope revealed an aneurysm of the ascending arch of the aorta. The boy's Wassermann test was 4 plus and the mother's reaction was 4 plus. In the epigastrium was a hard mass, about six cm. in diameter, movable and not tender, probably a gumma. The case was reported because of the great rarity of aneurysm of the thoracic aorta in children, there being only about 20 cases reported in the literature. The etiology in the majority of cases was very indefinite. So far as the writer had been able to ascertain, this was the first case in a child of unquestionable proven leutic aneurysm. The patient had been treated with 2 per cent. unguentum hydrargyri and up to the present time no improvement was noted.

Congenital Disseminated Atelectasis with X-Ray Findings.—Dr. JOHN RUHRÄH of Baltimore reported this case, because in the experience of at least three *x*-ray establishments in Baltimore not a single instance of this condition had been discovered. The patient was a girl, born July 27, 1917, who gained normally for a short time and then her weight became stationary. When first seen on November 15, 1917, the child had already passed through the hands of four doctors, and had been regarded as a case of difficult feeding. On examination a certain amount of cyanosis was observed which became very marked on crying. There was clubbing of the fingers and toes and a curious duskiness of the skin of the abdomen and enlarged superficial veins running up the chest. The most striking feature was the rapid respirations, rarely under 50, and many times 75 or 80 or more. The heart was normal as far as could be determined. The *x*-ray plate showed disseminated patches of unexpanded lung. With proper care and attention to feeding the child gradually improved. At present she weighed 25 pounds and was apparently normal.

A Case of Scorbutic Hematuria.—Dr. PERCIVAL J. EATON of Pittsburgh reported this case, which he was called to see because of suspected stone in the bladder. The child had had a history of hematuria for several weeks, and had been fed on patent foods and then on cooked foods, but never on fresh food. The child had no scorbutic symptoms so far as its gums were concerned. It was not particularly sore on being handled. However, the condition seemed to point more toward scurvy than calculus, and the child was accordingly given a diet of fresh, raw milk, beef juice, and orange juice. The hematuria rapidly disappeared and the child made a good recovery. This was the second case of scorbutic hematuria which the writer had seen. He had not looked up the literature, but was under the impression that such cases were rare.

A Case of Calculus.—Dr. PERCIVAL J. EATON of Pittsburgh reported this case, which occurred in a boy, 6 years of age, who gave a history of incontinence by day as well as night. At first there was no pain on urination and then later paroxysmal pain became more and more severe. A recent circumcision had not relieved the incontinence. The usual methods of treatment had no effect on the incontinence. The *x*-ray showed a good-sizd oval stone in the bladder. Its presence was confirmed by the sound. Through a suprapubic incision an 18.25 gram stone was removed. The boy made an uneventful recovery. The history of the boy revealed no apparent reason for the occurrence of the stone. He had not lived where the water was hard. The case was also interesting because of the long time the stone occupied the bladder without producing symptoms.

A Case of Anomaly of the Diaphragm with a Gastric and Intestinal Obstruction.—Dr. LAURENCE R. DEBUYS of New Orleans reported this case. He said the child, four months old, gave history of having been well up to the age of three months, when she had a peculiar attack of colic with twisting and straining. She had had two similar attacks, having been admitted to the hospital after the last one. At the time of admission to the hsopital she was acutely ill, with rapid respiration and pulse. Inspection showed less movement of the left side of the chest both anteriorly and posteriorly. Resiliency was absent on the left side. The heart was displaced to the right. The apex beat was in the median line. The abdomen presented a tumor in the epigastrium and left hypochondriac region, about the roundness of a banana and three or four inches long. The radiograph showed an obstruction suggestive of intussusception. An operation for the relief of the obstruction revealed a diaphragmatic hernia. On palpating the tumor there was a sudden gush of blood-tinged watery fluid through the mouth and nose. At this point breathing ceased and all efforts at resuscitation

were futile. A complete exploration of the upper abdomen showed the tumor attached to the hilum of the liver. The transverse colon and greater omentum were found in the thoracic cavity. The tumor consisted of the pyloric portion of the stomach twisted on its axis at the hiatus behind the diaphragm. The transverse colon and omenum had slipped up behind the stomach. The left lung was collapsed but showed no evidence of pneumonia. The left suprarenal body was found enlarged and hemorrhagic. At the posterior left half of the diaphragm there was no attachment; there was a hard cord bridging over this area in dome-like manner. There was a second twist in the stomach anterior to the pyloric orifice. The twisting in these two portions of the stomach had cut off the circulation, resulting in gangrenous necrosis of stomach wall. A point of interest in connection with this case was the absence of tenesmus with bloody stools in an obstruction involving the descending colon which would exclude the diagnosis of intussusception. Another point was that the radiograph gave no evidence of air in the thorax. This hernia belonged to the false variety of the congenital type of diaphragmatic hernia, being differentiated from the true variety by not having a sac. In this instance there were two conditions not mentioned in the various classifications of diaphragmatic hernia, namely, strangulation and palpable abdominal tumor.

A Case of Trichiniasis.—Dr. HOWARD CHILDS CARPENTER of Philadelphia reported this case, which occurred in a boy of 13 years of age taken suddenly sick with diarrhea, vomiting, and pain in the epigastrium. Eight days later pains became general all over the body, with swelling of the muscles and pain on pressure or on motion. The child had been sick for three months at the time he came under the writer's care, and had been treated for various conditions, such as muscular rheumatism, growing pains, etc. Examination showed the muscles swollen, tender, firmer than normal, and hard infiltrations were felt in the masseters, biceps, triceps, and gastrocnemius. The history which was obtained revealed the fact that the onset of the illness occurred after eating raw sausage. Several other members of the family who were ill following the eating of this pork still showed high eosinophile counts three months after the infection. Because of the severity of the disease in this boy, the pork which he ate must have been heavily infested. One of the reasons frequently given why children have milder attacks was because of their peculiar susceptibility to diarrhea, which tended to eliminate many of the intestinal trichinæ. From the history of this patient and of the other infected children in this family epidemic, the statement that the disease was mild in children was not borne out, as three of the children had been extremely ill. The differential diagnosis had to be made from nephritis, typhoid fever, meningitis, rheumatism, influenza, bronchopneumonia, and pleurisy. A point on making the diagnosis from nephritis was that the edema which was present in trichiniasis was not seen in the scrotum or labia. The eosinophilia which was so important in making the diagnosis might persist for months after the infection. The eosinophils usually numbered from 10 to 35 per cent. This diagnostic aid was also available early in the disease, as an eosinophilia had been reported about the time the young parasites entered into the muscles. Other parasitic conditions were excluded by failure in repeated attempts to find the ova of any intestinal parasite in the stools, and the absence of any parasitic skin infections. It was interesting to note that this child three months after the infection still had a decided increase in his leucocytes (16,000) and still had a marked eosinophilia (15 per cent.). The writer believed that not a few cases of so-called muscular rheumatism were really chronic trichiniasis. Trichiniasis should not be overlooked in this delicatessen age, when the mother on her way home from the club all too frequently stopped and purchased bologna sausage for the family's supper. The prognosis was uncertain at first, but was usually good after the seventh week. The mortality varied widely, being given by different observers as varying from 6 to 22 per cent. The prognosis of the patient here reported was good as to life, but it would undoubtedly be months before he could be brought back to normal health as far as his general nutrition was concerned. There was no specific treatment for cases seen after the migration of the embryos. Salvarsan had been tried with no effect. Serum from convalescent animals had no curative value. The writer emphasized the importance of making microscopical examinations for trichinæ at autopsies in our children's hospitals.

Two Cases of Pyelitis and a Case of Suppression of Urine for Four Days.—Dr. ROWLAND G. FREEMAN of New York reported these cases. He stated that the first case of pyelitis occurred in a female baby about nine months of age, and was of interest because, while the child had constitutional symptoms from the pyelitis, each effort to cure the child, whether by the alkali treatment or by hexamethylenamin, seemed to make the condition worse both in respect to the fever and the number of leucocytes in the urine. Within three days after the cessation of treatment the urine became normal and the child apparently recovered, although it was left with pyelitis without constitutional symptoms. The child was finally cured at a later stage, when neither large doses of bicarbonate with the addition of Kalak water, nor the large doses of hexamethylenamin caused any apparent disturbance of the child's health. The second case occurred in a frail child who weighed only five pounds at birth, but who did well until the latter part of the first year, when she had an attack of colitis. She then did well until four years later, when she was found to have pyelitis. In this case, too, large doses of alkali failed to cure and the mother becoming discouraged withdrew the child from treatment. Two years later the child was brought to the writer because of an injury to the face from a fall. The urine at this time still showed the presence of pus. The child was seen only five times and again taken away. About six months later he was again consulted, the mother reporting that during the interval the urine had been smoky looking and contained blood. Examination of the urine showed the presence of large amounts of pus. The child had a blood pressure of 220. Bowel washings, laxatives, counterirritants, and small doses of hexamethylenamin were of no avail, and the child died in about a week. This case was of interest as showing the importance of curing, if possible, every case of pyelitis whether associated with constitutional symptoms or not, as well as the necessity for frequent examinations of the urine in order to detect such cases of pyelitis when present without constitutional symptoms. The third case was that of a boy three years of age who had an attack of colitis for several days and then passed very little water. A small specimen of urine, sent to the State Laboratory at Albany, was reported to contain albumin and casts. For four days there was complete suppression of urine, during which time there was an increasing edema. The family were assured that the child would probably recover and that the urine when passed would contain considerable amounts of blood for several days. At the end of the fourth day the boy began to pass urine and during the first two hours passed from one and a half to two quarts. From that time the boy gradually improved and entirely recovered. This case was interesting, Dr. Freeman said, not because of the long period of suppression, because suppression during a longer period had been reported, but because it was not associated with inflammation of the kidney, but was probably congestion or at least complete suppression of function.

A Few Roentgenograms Demonstrating Gastrointestinal Abnormalities.—Dr. CHARLES GILMORE KERLEY made this presentation, which included illustrations of elongated, displaced, and sacculated sigmoids, dilated stomachs, plates showing the different degrees of gastric retention in cases of pylorospasm, pyloric obstruction, etc. One point brought out by the roentgenograms was that where there was an elongated and sacculated sigmoid the emptying time of the stomach was always slow. There seemed to be an association between the emptying time of the stomach and that of the large intestine. These abnormalities were found in children who suffered from obstinate constipation; some had recurrent vomiting and acidosis. The pictures served to demonstrate the importance of having an *x*-ray picture taken in case of complaining of obstinate constipation and other gastrointestinal disturbances that did not yield readily to ordinray methods of treatment.

Acrocephaly with Deformities of the Extremities.—

Dr. E. A. Park and Dr. G. F. Powers of Baltimore presented this paper, which was read by Dr. Park. They stated that in 1908 Apert described a child who was the subject of acrocephaly and syndactylism, collected eight other cases, and put forward the combination as a clinical entity under the title of "Acrocephaly-syndactylism." Since that time two other cases of a similar nature had been reported. The writers had been able to collect from the literature more than 21 cases. The clinical picture was very striking, and not easily forgotten. The syndactylism did not differ, however, from the syndactylism occurring without malformation of the head, and cranial deformity did not differ from that in acrocephaly uncomplicated by syndactylism. All the writers on this subject discussed at considerable length the nature of the malformations of the skull, and agreed that it was due to premature synostosis of the sutures. No writer, however, seemed to have considered the malformations of the hands and feet. Several writers had sought to correlate the malformation of the skull and extremities as being both due to hereditary syphilis or amniotic adhesions; others had left the malformations of the head undetermined, but had explained the malformations of the extremities as being secondary to the malformations of the head, either as a result of the injury of a center situated in the base of the skull or contiguous portion of the brain governing the growth of the extremities or to interference with the normal development of the hypophysis. The writers of this paper did not believe that the cranial deformity in acrocephaly was produced by premature synostisos of the cranial bones, or that the malformation of the extremities could possibly be regarded as secondary to the malformations of the skull. They brought forward embryological evidence indicating an origin altogether antedating ossification. It was not generally appreciated that malformations of the extremities, other than syndactylism, not infrequently occurred in the subjects of acrocephaly. In other words, acrocephaly tended to have in association other skeletal defects, and no such clinical entity as "acrocephaly-syndactylism" existed.

Dr. Charles Herrman of New York stated that in trying to explain these anomalies it was important that congenital syphilis should not be emphasized as an etiological factor. There was scarcely a paper written on this subject that did not lay stress on the importance of congenital syphilis as an etiological factor. The finding of a negative Wassermann in these cases had proved that they bore no relation to congenital syphilis. The same was true in regard to achondroplasia. Most writers on this subject emphasized the part played by some abnormality of the pituitary. In these congenital anomalies they were dealing with an entirely different phenomenon. There was no doubt but that heredity played a part in polydactylism. It was not necessary that the identical anomaly should be reproduced in order to show a hereditary factor. It simply meant that there was an anomalous tendency in the family which showed itself in various ways.

Dr. Park stated that there was no family history of anomaly in this case and no history of a defective germ plasm.

The Incidence and Significance of the Rheumatic Nodules in Children.—Dr. Joseph Brennemann of Chicago read this paper. He said that the rheumatic nodules that had received so much attention from British writers on rheumatism in children were almost universally considered a rare condition in this country. As a result of his own observations he believed that they were just as frequent in this country as they were in England in an equal number of similar cases of rheumatism. The chief object of the paper was to stimulate an interest in the subject so that widely distributed observers might settle the question of whether these nodules were a definite quantitative accompaniment of rheumatism, or whether they had a very selective geographical habitat. He gave a detailed description of the morphology and distribution of the nodules and discussed their significance. They practically never occurred in rheumatism uncomplicated by endocarditis or pericarditis. They are relatively rare in mild cases of rheumatism or chorea with cardiac complications, but occurred with great regularity and usually very abundantly in chronic or recurrent and active endocarditis, especially in those cases that for weeks and months swayed between life and death, not alone because of a broken compensation, but even more because of a smouldering, uncontrollable infection that ever and anon lit up again. Inasmuch as rheumatic nodules were pathognomonic of rheumatism with carditis, they were often of considerable diagnostic value. A new and abundant crop also had often an ominous significance in showing that a new and serious cardiac invasion had taken place. Rheumatic nodules unless very carefully looked for were apt to be overlooked. The author believed that careful search would reveal them much more often than was commonly thought, and that the only reason they had attracted more attention in England than in this country was because they had more and severer rheumatism there than here.

Osteogenesis Imperfecta-Congenita.—Dr. H. M. McClanahan and Dr. W. W. Willard of Omaha reported this case. Dr. McClanahan stated that up to 1906, 140 cases of this condition had been reported. Lovett and Nichols, after studying these cases, concluded that only 14 of them were cases of true osteogenesis imperfecta-congenita. Two types of the condition were recognized, namely, osteogenesis imperfecta-congenita, and osteogenesis imperfecta-tarda. Osteogenesis imperfecta-congenita was a rare disease, characterized by imperfect bone development, numerous fractures, and excessive callus formation. After reviewing the various theories advanced to account for the condition, the writers concluded that whatever the theories, the fact was that bone formation from the periosteum remained in the fibrous state. The study of the bone in this case showed evidence that the osteoblasts rising from a fibrous bone marrow because of insufficient nourishment or some toxic influence did not develop properly, but remained polygonal and later underwent metaplasia into osteoclasts. The case reported was that of a male child, three months old, in whom the deformity was apparent at birth, when several fractures were present. At the time of admission to the hospital masses of callus could be felt on the shafts of the arms, thighs, and legs. The mother was certain the baby had grown. The bowels were regular, the urine free, and the Wassermann was negative. The von Pirquet was also negative. The baby remained in the hospital from October 1 to November 16, 1918, during which time its temperature varied between 103° and 105° F., and respirations from 60 to 90. The legs were constantly flexed and the arms were splinted at right angles to the body. Examination of the chest a few days before death revealed fine râles over the posterior chest with small areas of dullness on percussion. Death occurred from exhaustion on November 18. As far as the writer could ascertain, this was the youngest case with a fatal issue which had been reported in which a careful histological study was made. The conclusions reached by Dr. Willard agreed very closely with those recorded by Nichols upon an infant dying at the age of ten months. All the histological and post-mortem findings were recorded.

Dr. Joseph Brennemann of Chicago said they ordinarily thought of these cases as being in a serious condition. He had seen one child with this condition who appeared to be in normal health. In this instance, after some nutritional disturbance the child's arm became sore, and it was found to have a flail joint. A few days later the other arm became sore. The *x*-ray showed that all four bones of the forearm were fractured, the fractures being absolutely transverse. The child was kept under observation, and no other fractures occurred.

Dr. L. Emmett Holt of New York recalled the case of a child eleven months old who had a fracture at the middle of the tibia. Six months later a fracture occurred on the other side. The *x*-ray taken at this time showed that there had been a fracture in the meantime that was not resognized by symptoms. Another case coming to the hospital some time ago was diagnosed as a case of scurvy because of the tenderness over the bones. The *x*-ray examination showed typical fractures. It was apparent that heredity was of some importance in these cases. This type of fracture had nothing in common with the green stick fracture.

Dr. Charles Herrman of New York stated that only

about one-half of these cases gave a family history of fragility of the bones; it was probable, however, that there was a hereditary factor. It was not only the bones that were abnormal but the ligaments, and other structures. Another feature in these cases was the blue color of the sclera, which was present in about one-half of the cases; this also showed that the condition was a disease not confined to the bones, but that probably all the tissues of the body were somewhat abnormal.

Care and Treatment of Whooping Cough Patients.—Dr. JOSEPH WINTERS of New York read this paper, in which he cited statistics showing the high death rate from whooping cough. He said that in 1916 it caused almost as many deaths as scarlet fever and typhoid fever combined, both in New York City and New York State. In 1917 it caused almost twice as many deaths as scarlet fever. Three-fourths of the deaths from whooping cough occurred in children under one year of age. It caused more deaths during the first year of life than any other disease. During the first year of life whooping cough was carried to the child in clothing infected by the whooping cough patient. Carelessness in attendants disseminated it. Prevention in children was permanent prevention, as immunity was attained at about the tenth year. Adults supposed to have whooping cough were usually cured by purgation and the cough shown to be a digestive reflex cough. The whooping cough patient should be kept indoors at a temperature of 65 degrees F., with fresh air but no draft. The bedroom must not be cooler than 65 degrees F. Variations in temperature induced repeated coughing attacks and complications, and it was the complications that were responsible for most of the fatalities of whooping cough. Codeine and bromides might be given. After whooping cough children were extremely susceptible to repeated attacks of bronchitis and were also predisposed to tuberculosis.

Dr. SAMUEL S. ADAMS of Washington took issue with several of the statements made by Dr. Winters. He said he felt that many could not accept the statement that whooping cough was conveyed by the clothing. He recalled a symposium on whooping cough before the Society some years ago. At that time the consensus of opinion was that climate did not have much influence on the course of the disease, that the child with whooping cough should have good food, fresh air, and hygienic surroundings and should then be left alone so far as treatment was concerned. As to the treatment of whooping cough with vaccines, a variety of opinions were expressed in the literature. He was of the opinion that vaccines had no effect in preventing the disease or in controlling the paroxysms. Some children got along well without much treatment while others required nerve sedatives. He could see no reason for making a mistake in differentiating a digestive reflex cough from the paroxysmal cough of whooping cough.

Do Calories Measure the True Values of Foods?—Dr. HENRY DWIGHT CHAPIN of New York presented this communication. He stated that the caloric method of feeding was based on the assumption that nutrition processes depended solely on the oxidation of food and that heat given off as the result of oxidation was the measure of the value of food. In practice the tendency was to keep a table of caloric values and the diet was laid out by arithmetic. The physician was apt to think that if the caloric count was correct the food problem was correctly solved. In the experimental study of nutrition it was soon found that nutrition was not a simple oxidation process. Bayliss stated that heat and combustion did not necessarily give accurately the energy of foodstuffs as available in the organism. In the animal body energy which was the result of chemical combinations was converted into various other forms without the necessity of passing through the form of heat. Large quantities of the common foods consumed by animals were used by anaerobic organisms, as the air was not essential for animal life in all cases. Food must be selected for its right physiological value for each individual. That what was the right physiological value for one individual might not be right for another might be due to anaerobic metabolism in one instance and aerobic metabolism in the other. The system of teaching must be constructed so that it was based on the knowledge of the physiological properties of the various food elements and the fact that there were mixed types of metabolism. It was hence a question whether it was not time to weigh the caloric method of feeding and possibly abandon it.

Dr. FRITZ B. TALBOT of Boston said that, while he disliked to disagree with Dr. Chapin, he thought that all physiologists were agreed that conclusions drawn from observations made on animals could not always be applied to living children. He could not agree that oxygen was not necessary in the presence of muscular contractions. It had been conclusively proven in the Carnegie Laboratory that every time a muscle moved it increased the production of carbon dioxide, and carbon dioxide could not be formed without oxygen. The trouble that had come from the caloric method of feeding in the past was due to lack of knowledge of the foundation upon which it was based. The assumption that in using the caloric method of feeding one was using an accurate method was very inaccurate. In their experiments they had found out a number of facts not generally known. One of these was that the caloric value of lactose was not 4.1, as was usually given, but 3.7. Another factor to be taken into account was the loss of a certain amount of food in the feces. Energy was also used in the digestion of food. For instance, if 100 grams of lactose were given, seven were used in the preparation of the remainder for use in the body. Twenty per cent. of all protein taken in was consumed in making the remainder ready for use. As to the caloric method in relation to infant feeding, the baby must first be fed what agreed with it and what it could digest. In the second place, it must have food that was well balanced. In the third place, one must see that the baby got enough, and when a normal baby was getting enough food that agreed with it and was well balanced it was getting what the physiologist showed was the proper number of calories. Dr. Talbot emphasized the point that while he did not believe in any method of feeding, he did not think they should omit anything of value in determining whether a baby was getting what was correct or not, and the determination of calories sometimes helped.

Dr. J. P. SEDGWICK of Minneapolis said that he also felt that the determination of the caloric value of food was a very valuable aid in estimating the quantity of food an infant was getting. But the estimation of the caloric value of food was not a method of feeding. One could feed protein or fat or carbohydrate entirely and still have the requisite number of calories, hence it was very incorrect to use the term "caloric method of feeding."

Dr. F. W. SCHLUTZ of Minneapolis said he also felt that the caloric measure of food was something they should not altogether discard, since it was about the only way they had of measuring the intake of food. It was, however, a mathematical measure and not a method of feeding.

Dr. W. MCKIM MARRIOTT of St. Louis said that another difficulty in the use of the caloric estimation of the food intake was that they had not estimated the amount used by the energy output, which might be very variable in different individuals. He thought that the error was not in the caloric measure of food but in the fact that their method of making the estimations was wrong.

Dr. L. EMMETT HOLT of New York said he was glad this subject had been brought up in order to let them all know that the estimation of caloric values of foods was not a method of feeding. When Dr. Roche introduced percentage feeding it came by misnomer to be known as "the percentage method"; in the same way the caloric measure of food had come to be known as the "caloric method." The estimation of percentages was exceedingly important, and he regretted that it had been lost sight of. It seemed to him of the utmost importance in balancing diets that they should know what part was fat, what part carbohydrate, and what part protein. Likewise the caloric estimation of food values was of importance, but it was a method of statement and not a method of feeding.

Dr. CHAPIN, in closing, said he could not agree with Dr. Talbot's statement that observations on lower animals could not be applied to human beings. That was an error frequently made. One cell lived and breathed and grew just as did a higher cellular animal. Evolu-

tion started with the living cell and went up. One of the serious errors physicians had been making was that of detaching the higher from the lower in animal life. He thoroughly agreed with the statement that the caloric determination of the food value alone was a very inaccurate method of feeding. His reason for bringing it up was not primarily for the members of the American Pediatric Society, but for those not so well informed. There were many men all over the country writing out calories and feeling that the final solution of infant feeding had been reached. The important point he wished to bring out was that many processes of life might take place without oxidation, and if we accepted that fact it threw off a great deal of the value of the estimation of calories.

A Study of the Stools of Institutional Children to Determine the Existence of Intestinal Parasitic Infection—Dr. LAURENCE R. DEBUYS of New Orleans made this presentation, based on the study of 597 children in seven institutions. He said that the frequency of the infections by the various parasites in the order named were: *Trichuris trichiura, Ascaris lumbricoides, Hymenolepis nana, Oxyuris vermicularis, Strongyloides stercoralis, Necator americanus,* and *Hymenolepis diminuta.* The hygiene, general care, duration of residence in the institutions, previous environment, association with dogs, eating of dirt, and absence of systematic medical inspection seemed to have a direct bearing upon the frequency of intestinal parasitic infection. The two institutions where systematic medical inspection was made showed the lowest percentages of infection. The two institutions with the heaviest infections were those in which the population was transient and where there were no medical inspections, the infections in these institutions being 94.2 per cent. and 83.33 per cent. respectively. The youngest child infected was two years of age and was an inmate of the least sanitary of the institutions. This child had a quadruple infection. The relation of age to infection seemed to be negligible, except that there were no infections among infants. The maximum number of infections was at 11 years of age. The maximum age of infections in boys was 11 and 12 years and in girls 13 years. The symptoms usually attributed to "having worms" were as frequent, and some a little more frequent, in those not infected than in those infected. The eosinophilia was a valuable aid in the diagnosis of infection with intestinal parasites. It was, however, not pathognomonic and its absence did not exclude an infection. The eosinophiles were found as high as 28 per cent. in the positive cases and 18 per cent. in the negative cases. No parasite in this study seemed to have a definite eosinophilia. Infection by any of the parasites in this study could exist with an absence of eosinophiles. This was found in their single infections with the exception of the *Necator americanus* and *Hymenolepis diminuta. Necator americanus* was found in single infections in only two cases, in which instances the eosinophiles were 12 and 13 per cent. respectively. However, in mixed infections of this parasite with *Trichuris trichiura* and *Hymenolepis nana* the eosinophiles were as low as one per cent. *Hymenolepis diminuta* was not found in single infection, but in combination with *Trichuris trichiura* and *Ascaris lumbricoides* the eosinophile count was 13 per cent. Minimum eosinophile counts in double and triple infections were 0 per cent., while the maximum was 28 per cent in each. Two quadruple infections upon which blood counts were made showed 8 and 9 per cent. eosinophiles, respectively. The only way in which to make a positive diagnosis of the presence of intestinal parasites was by either finding the parasites or the ova in the stool of the individual. Vermifuges should therefore not be given to the defenceless child unless it was known that the infection existed and its character was ascertained, when the specific drug might be given to combat the particular infection.

Dr. J. P. SEDGWICK of Minneapolis emphasized the need of medical inspection in institutions, and said that if intestinal parasites were looked for systematically they would be found oftener than was thought.

Dr. JOSEPH BRENNEMANN said that in the United States when one spoke of "worms" they usually thought of *Ascaris lumbricoides;* nevertheless, he had heard Dr. Kerley say that he had met with this parasite only a few times in New York City. Patients coming under his observation with this parasite had shown no characteristic symptoms, and the presence of the parasites was not recognized until they were found in the stools. He would like to know whether the others had observed symptoms attributable to these parasites.

Dr. OSCAR M. SCHLOSS of New York said that he had examined many cases for intestinal parasites, and had classified them. He thought the symptoms depended upon the grade of infection. Occasionally there were very distinct symptoms. He recalled one instance in which the child had a very severe diarrhea with blood and mucus in the stools without apparent cause. In this instance it took months of heroic treatment to get rid of the parasite, and long after the infection was cleared up the ova continued to be found in the stools. The *Oxyuris vermicularis* might be present in great numbers without causing symptoms. In the ordinary life cycle of this parasite the ova were not discharged, and the only way they could be demonstrated was by the administration of santonin. One symptom to which Sill had called attention was pain in the right iliac region. In several instances he had seen marked anemia due to the presence of the dwarf tapeworm. The symptoms, however, in proportion to the amount of infection, were very slight. It was very uncommon to find intestinal parasites in private patients in New York, but they were quite common in certain classes of dispensary patients. The dwarf tapeworm was frequently found among Italians. This parasite was very common in certain parts of Italy and Sicily, where in certain districts as many as 10 per cent. of the population were said to be infected.

Dr. HOWARD CHILDS CARPENTER of Philadelphia described an epidemic of *hymenolepis nana* in an institution in Philadelphia, where they had made a careful study to determine, if possible, the mode of transmission. They had trapped and examined rats, but found them normal so far as this parasite was concerned. It seemed to him that the transmission was from one child to another, a direct hand-to-mouth infection. It was well to remember that scabies might also cause an esoinophilia.

Dr. W. MCKIM MARRIOTT of St. Louis cited a case in which a boy was operated on for appendicitis, and examination of the appendix showed that it contained the *Oxyuris vermicularis.* Of course usual method of treatment would have no effect on the parasite in this locality.

Dr. A. G. MITCHELL of Philadelphia said that he had observed a number of children in France, where infection with the *Ascaris lumbricoides* was very common. Some of them had acute symptoms which cleared up when the infection was eliminated. Some gave gastric symptoms when the worms got into the stomach, and others had intestinal symptoms. Whether the worms were the cause of the symptoms he could not say, but he knew that the general nutrition of the children improved when the infection was eliminated.

Dr. E. A. PARK of Washington, D. C., related his experience with intestinal parasites in France. There they had made it a routine procedure to examine the stools for intestinal parasites. He described an investigation carried out on 50 cases infected with *Ascaris lumbricoides* to ascertain if there were symptoms that could be definitely attributed to the parasites. They had found that the symtoms disappeared when other conditions were made normal. It was extremely difficult to get rid of the parasites.

Dr. DEBUYS, in closing, said it was his impression that a great many of these parasites did not cause symptoms. The American hookworm caused anemia, and interfered with growth and development. He had seen the *Ascaris lumbricoides* cause severe symptoms. He knew of one instance which was found at operation in the appendix. He had known it to cause intestinal obstruction, and in one case it had loosened a Murphy button. The finding of the *Oxyuris vermicularis* in the appendix was interesting, as that parasite was not usually found so high up in the intestinal tract. *Hcmenolepis nana* might be overcome by the use of male fern.

Dextrose Tolerance in Atrophic Infants.—Dr. H. F. HELMHOLZ and Dr. L. W. SAUER of Chicago presented this paper which was read by Dr. Helmholz. He stated

that in making their investigations they had used the Woodyatt apparatus and a dextrose manufactured by the Corn Products Company. Solutions of approximately 10, 15, and 20 per cent. were used, the actual concentration being determined polariscopically. It was immaterial so far as tolerance was concerned whether 10 grams of glucose was injected in a volume of 10 c.c. or in a volume of 100 c.c., provided it was injected evenly in a given unit of time. At the start a rate of injection was chosen that would not be likely to exceed the tolerance, for if the sugar appeared at the first rate of injection the injections had to be resumed on a subsequent day. If no urine was obtained after thirty minutes, glycosuria would not occur even after several hours of continuous injection. The rate of injection was increased by one-tenth of a gram per kilo per hour until sugar appeared in the urine. Injections were made in five infants who were nearly normal weight for their ages, and the tolerance of these did not exceed 1.1 gram per kilo per hour. In contrast to these findings the tolerance of atrophic infants ranged from 1.5 to 1.8 per kilo per hour. While the number of cases observed was too small to warrant any definite conclusions as to the possible therapeutic value of the intravenous injections of glucose, in two cases the injections were followed by gain in weight without change in diet; in one case there was a gain in weight, but the diet had also been changed, and in three cases there was no beneficial effect. It would appear that the sugar tolerance of normal infants did not differ much from that of normal adults. The tolerance of atrophic infants for glucose given intravenously was considerably greater than that of normal infants.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

MANUAL OF OBSTETRICS. By EDWARD P. DAVIS. 478 pages with illustrations. Published by W. B. Saunders & Company, Philadelphia.

PATHOGENIC BACTERIA AND PROTOZOA. By JOSEPH MCFARLAND. 829 pages with 30 illustrations. Published by W. B. Saunders & Company, Philadelphia.

PRAKTIKUM DER GERICHTLICHEN MEDIZIN. By HUGO MARX. 293 pages with 25 illustrations. Published by August Hirschwald, Berlin.

Therapeutic Hints.

Treatment of Bronchial Asthma.—In a letter to the editor, W. B. Crawford, of Goldsboro, N. C., reports the successful use of "almost a specific for asthma," the formula of which he found in an old notebook belonging to a deceased uncle, and credited to *The Medical Summary* of more than a quarter of a century before. The prescription, which was used in a distressing case of bronchial asthma, in a patient nearly seventy years of age, and which was "simply magical" in its effects, is as follows:

℞ Tincture gelsemium ..... ℥j
Tincture lobelia ..... ℥j
Potassium bromide ..... ℥ss

M. Sig.—Twenty drops in water every three hours. —*The Medical Summary.*

Treatment of Acne Vulgaris.—Levin holds that acne vulgaris is a hyperkeratosis of the skin associated with a disturbance of the carbohydrate metabolism, usually accompanied by gastrointestinal derangements. The acne bacillus, if it is an etiological factor, becomes active only upon the development of a favorable soil for its growth. The general treatment of the condition, therefore, includes all the procedures employed for the detection and correction of abnormal functioning of the internal organs. The local treatment includes measures for the removal of the thickened horny tissue and the grease and cell detritus; to improve the cutaneous circulation, and to prevent and remove infection. In the office the skin is scrubbed with benzine to remove dirt, grease, and cell detritus, and to aid in loosening comedones, followed by mechanical extraction of comedones. The smaller pustules are opened. The promotion of hyperemia by the use of suction cups is sometimes beneficial. The skin is subsequently cleansed with alcohol and tincture of iodine applied to the interior of the ruptured and incised lesions. The ultraviolet rays emitted by the mercury vapor lamp are then employed, the applications being made at intervals of from five to seven days. For the home treatment, before going to bed at night, after washing the affected skin with hot water and soap, then with cold water and soap, and the extraction of as many blackheads as will come away easily, the following lotion is to be rubbed well into the skin for ten minutes, with a piece of flannel:

Zinc sulphate .....℥i-℥iv
Rose water ..... ℥ii
Mix and add,
Potassium sulphate .....℥i--℥iv
Rose water ..... ℥ii

For boggy and indurated masses, and folliculitis of acne keloid, which at times accompanies acne vulgaris, Levin recommends the following ointment:

Sulphur ointment ..... ℥iii
Red oxide of mercury ointment.....℥iss
Zinc oxide ointment.....q. s. ad ℥i

—*New York Medical Journal.*

Ringworm of the Scalp.

℞ Iodine ..... ℥i
Rectified oil of tar..... ℥i

Mt. et ft. pasta. Sig.: Apply every six or seven days, washing the scalp with mixture of green soap before removing the application.—Coster.

DIAGNOSTIC PITFALLS IN PULMONARY TUBERCULOSIS.*

BY MAURICE FISHBERG, M.D.,

NEW YORK.

CLINICAL PROFESSOR OF MEDICINE, UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE; ATTENDING PHYSICIAN MONTEFIORE HOME AND HOSPITAL FOR CHRONIC DISEASES.

ABOUT fifteen years ago we were taught that one of the most important duties of the physician to his patients is to diagnose tuberculosis in its early stage, and that neglect in this regard is in a great measure responsible for the high mortality caused by the tubercle bacilli. As a result of this warning the vast majority of practising physicians have been on the alert, and have diagnosed tuberculosis on the principle that it is better in doubtful cases to keep the patient under treatment, urge a vacation, or admit him to a sanatorium, than to overlook a tuberculous lesion in the lungs and thus deprive him of the benefits of early and prompt treatment. That this policy has not been satisfactory to either physician or patient is shown by the fact that most writers on the subject at present insist that there are many diseases which simulate pulmonary tuberculosis to an exquisite degree, and that it is important that every practitioner should be on the alert in all suspicious cases, thus avoiding the isolation of persons who suffer from non-tuberculous pulmonary diseases and sparing them the troubles, tribulations, and expense of treatment of tuberculosis.

The recent World War has shown that not all who have heretofore been classed as "suspects," or "incipients," must be subjected to the hardships and expense of modern treatment for tuberculosis. A large proportion of such individuals were admitted into the various armies and they made good. And if many "suspects" survived the hardships of war we may safely conclude that they could easily be treated at home and both the patients and society would be gainers.

But while attempting to differentiate tuberculosis from diseases which simulate it, there are many pitfalls in the way of the physician who conscientiously pursues his calling. He is loath to pronounce a patient tuberculous without positive proof of the existence of active disease in the lung, but he fears failure to diagnose this disease when it actually lurks in the lungs, thus working havoc by postponing proper treatment; and while this is not always as deadly as has been stated by some writers, yet it is, in many cases, quite dangerous to both the patient and the physician, at least to the latter's reputation.

It is my object to-night to indicate briefly the pitfalls which are likely to be met with by the average physician in his daily practice and to indicate some ways of avoiding them. In dealing with the subject I shall try to show you the pitfalls into which I have at various times fallen myself, and the lessons I have learned while being in these holes. You know how often a physician learns from mistakes; usually more than from so-called brilliant diagnoses.

Experience has taught me that bias has had the most baneful influences in our attempts at differentiation of the chronic diseases of the lungs. Because pulmonary tuberculosis is a very common disease, of frequently insidious onset, and because of the importance of prompt diagnosis, it has been suspected in every case of cough, blood spitting, emaciation, etc. While it is important to bear it in mind when considering an obscure case, it is more important to remember on all occasions that there are many causes of mild fever, cough, emaciation, hemoptysis, singly or collectively, and that pulmonary tuberculosis is but one of these causes. With tuberculosis, as is true of all other matters of diagnosis, the physician who approaches his patient with an open mind, and is influenced only by real clinical facts, carefully observed and correlated, will avoid pitfalls. If you are not biased in favor of tuberculosis, you will very often be surprised to find that your patient who spits blood is troubled with disease of the heart, kidneys, bronchi (bronchiectasis), or simply of the rhinopharynx; you may even be amazed at times to find that the blood expectorated is derived from the posterior nares, in some cases of epistaxis.

Very few physicians are biased against tuberculosis when the family history of the patient shows that none of his blood relatives and collaterals have ever had the disease, but many are liable to diagnose this disease in obscure cases merely because there have been other cases in the family. Of course, familial tuberculosis, which is rather common, is responsible for this prejudice. But we have all observed that not all the offspring of tuberculous parentage develop phthisis. In fact, statistics have distinctly shown that a family history of phthisis may be elicited among non-tuberculous patients almost as frequently as among tuberculous.

In a doubtful case do not diagnose tuberculosis merely because you elicit a history of exposure to infection. There are so many tuberculosis "carriers" in any modern industrial city, that I would like to be shown a man or woman who has never

*Read before the Williamsburgh Medical Society, Brooklyn, N. Y., December 8, 1919.

been in contact with a tuberculosis patient. Because a man died from tuberculosis do not pronounce his wife tuberculous when she coughs or loses in weight during the first few months of widowhood. Despite the intimate contact with a tuberculous person, conjugal tuberculosis is exceedingly rare. I have seen but few cases. Similarly, physicians and nurses whose work is mainly conducted in hospitals and sanatoriums for tuberculous patients have hardly ever been observed to contract the disease while pursuing their vocation. You will avoid a diagnostic pitfall by disregarding altogether exposure to tuberculous infection in adults.

When noting signs of tuberculous disease of the glands, joints, or bones do not hastily diagnose pulmonary tuberculosis when your patient coughs. Scars of this nature are diagnostic pitfalls. If you bear in mind that chronic pulmonary tuberculosis is exceedingly rare in persons showing such scars on the neck, or deformities of joints or bones, you may avoid the trap.

A diagnostic trap, into which many physicians fall and drag their patients with them, is a history of some disease which is reputed to be of etiological moment in tuberculosis. Among these, pleurisy and influenza are perhaps the most important. It is well known that the vast majority of cases of pleurisy are tuberculous in character, and more than fifty per cent. of patients suffering from so-called idiopathic pleurisy, dry or moist, subsequently develop pulmonary tuberculosis. But we are apt to forget that nearly fifty per cent. pass through life without ever becoming tuberculous in the clinical sense. It is therefore wrong to tell every patient with pleurisy that he is surely doomed to succumb to tuberculosis in the near future. If he, after recovering from the acute pleural inflammation, does not cough, has no fever, and maintains his normal weight or gains, he is to be considered well for the time being, though he may be warned that in case he begins to be annoyed by any of the symptoms of tuberculosis he should at once call for a careful examination and study of his case. He may also be told that in the event he does develop pulmonary tuberculosis, the fact that he had had pleurisy is very much in his favor; the disease is likely to pursue an exceedingly chronic course and tend to recovery.

Contrary to the teachings of writers of previous generations, the recent epidemic of influenza has shown that this disease is not etiologically related to tuberculosis. Of the hundreds of cases which have come under my observation during the past year in which cough, expectoration, fever, etc., have persisted after an attack of influenza, only one turned out to be tuberculosis. The pulmonary sequelæ of influenza are hardly ever tuberculous in character. Most of these patients suffer from bronchitis, bronchiectasis, pleurisy, abscess of the lung, etc. They should not be considered tuberculous, and should not be banished to distant climes or to sanatoriums. If you will bear this in mind you will avoid one of the most common diagnostic pitfalls in your way.

I have already mentioned the hemoptoic pitfall. But it will bear repetition that while the vast majority of patients who spit blood suffer from tuberculosis, there are many who do not. In about one-third of the patients with hemoptysis who have consulted me within the past three years the etiology was altogether different. Perhaps the most frequent cause, after tuberculosis, is heart disease, especially mitral stenosis. Patients with mitral stenosis often cough, lose in weight, have mild fever, spit blood, and show physical signs of a localized lesion in the lungs. They are very frequently treated for tuberculosis by physicians in the municipal clinics, and kept in sanatoriums for months. Considering that the symptoms may be relieved by the judicious administration of digitalis or its congeners, it is obvious that this diagnostic pitfall is a very serious one. Moreover, this pitfall may be avoided by carefully examining the heart in each case presenting pulmonary symptoms, especially hemoptysis. When you find the rate of the pulse slow, perhaps more or less irregular, when the volume of the heart is made out larger than normal, and on auscultation a presystolic murmur or a slapping first sound is audible; when the main subjective symptoms complained of are dyspnea on slight exertion, palpitation, congestion of the face and lips, edema of the ankles, etc., you may make up your mind that heart disease is responsible for the hemoptysis and not tuberculosis. And never diagnose tuberculosis in the presence of mitral stenosis unless the sputum contains tubercle bacilli. Cardiacs, with the exception of those suffering from pulmonary stenosis, hardly ever develop active pulmonary tuberculosis.

Pulmonary infarction is another not very uncommon cause of more or less copious hemorrhage, and the site of the infarction may show signs of a localized lesion in the lung,—dulness, feeble or bronchial breath sounds, and later moist râles, all localized and circumscribed over a limited area of the chest. But a careful examination of the heart and blood vessels will clear up the diagnosis in practically all cases.

It is not generally appreciated that patients suffering from pulmonary emphysema and bronchitis at times spit blood. This is especially true of patients with chronic bronchitis and bronchiectasis. Those with bronchiectasis may bleed very copiously for days. Of course it is precarious to diagnosticate these cases as tuberculosis, as is often done. This diagnostic pitfall may be avoided by paying attention to the following points: In diffuse bronchitis the percussion findings over the upper lobes of the lungs are negative while on auscultation adventitious sounds will be discovered all over the chest. It is commonly secondary, and a cause should be sought and found—heart disease, nephritis, pulmonary emphysema, etc. The toxic symptoms of phthisis are lacking, there is no fever, no tachycardia, etc., and the blood pressure may be rather high, though the patient coughs and expectorates profusely. With such diffuse tuberculous lesions emaciation is the rule in tuberculosis, while in bronchitis the patient may appear well nourished.

Bronchiectatic lesions are commonly found in the lower lobes of the lungs. And if you want to avoid one of the most dangerous diagnostic pitfalls, do not diagnose tuberculosis in a patient whose lesion is localized in one of the lower lobes of the lung exclusively, unless you find tubercle bacilli in the sputum, and this will occur only on exceedingly rare occa-

sions. In other words, if you find that the resonance and breath sounds over the upper lobes are normal and adventitious sounds are lacking in those locations, do not diagnose tuberculosis, no matter what signs are elicited over the lower lobes of the lungs. Moreover, in cases with tuberculous lesions in the lower lobes, a lesion will almost invariably be found in one of the upper lobes and the constitutional symptoms will be clear cut—cadaveric appearance due to emaciation, a hectic flush, fever, nightsweats, tachycardia, etc. With bronchiectatic lesions, as a rule, the general condition, the nutrition of the patient leaves little to be desired; he may be rather stout, and the rate of the pulse may be normal, a phenomenon very infrequent in tuberculosis with cavities in the lower lobes of the lungs. Clubbed fingers in these cases speak in favor of a non-tuberculous lesion.

Finally I should mention that hemoptysis is very often an annoying symptom of congestion of the posterior nares and tonsils. Most of the streaky sputum which often alarms a patient and, at times, a physician, is derived from the throat. In many cases a careful inquiry reveals that there was epistaxis, but in a large proportion of this class of cases the blood, derived from the back of the nose, trickles down into the throat and is expectorated. A careful examination of the posterior nares should be made in every case of streaky sputum. A history of an acute rhinopharyngeal condition speaks against tuberculosis.

You will be surprised when I also speak of hematemesis as a source of error in this regard. But when you find that many a keen and experienced clinician at times is unable to decide at once whether large quantities of blood brought out by a patient are derived from the stomach or the lungs, you may in some cases give some thought to this problem. The differential signs given in text books are clear cut to be sure. In hematemesis the blood is vomited, in hemoptysis, it is coughed up. So far so good. But many tuberculous patients swallow the blood and then vomit it out again. On the other hand blood derived from the stomach may be aspirated and then coughed up. Whether the material brought out is alkaline or acid in reaction is immaterial in these cases. In several cases, seen for the first time, I have been unable to decide the source of the blood. But there is one sign which is very helpful. Watch your patient for a day or two. If, after the large gushes of blood have ceased, he keeps on expectorating streaky sputum for several days, the blood came from the lungs. On the other hand, if the patient in whom the physical signs are indefinite, has a large hemorrhage which suddenly stops, and then no streaky sputum is brought out, the blood in all probabilities was derived from the stomach; you may then find the stools contain blood. However, blood may be detected in the stools of tuberculous patients who have swallowed same during a pulmonary hemorrhage.

We have yet to consider the most serious pitfall in the diagnosis of tuberculosis and one into which many a physician has fallen. I refer to the signs elicited by physical exploration of the chest. There are thousands of persons in this country who have been wrongly deprived of the benefits of life insurance, numerous families have been broken up, and a multitude of individuals have become hypochondriacs because of faulty interpretation of signs found by physical diagnostic methods.

In this regard the diagnosis of tuberculosis is not unique. There was a time, not so very long ago, when a physician, hearing a murmur over the cardiac region immediately pronounced his patient dangerously sick with heart disease. Sir James Mackenzie strongly emphasized the fallacy of this assumption that murmurs are invariably positive signs of diseased hearts requiring treatment. You probably recall his brilliant remarks on this subject: "It is questionable whether the discovery of auscultation so far has done more harm than good. Human nature is so constituted that the evil is usually associated with what is mysterious. This particularly applies to noises and sounds whose cause is unknown. The modification of the sounds which are perfectly consistent with a healthy heart has never been thoroughly understood, and in consequence a false standard has been set up of what is normal and what is pathological. As a result we find a great many perfectly healthy people looked upon as diseased, and treated as suffering from a serious complaint, and their future life restricted, because of the presence of some signs, as a murmur or an irregularity, which owing to an imperfect knowledge of the real nature of the sign, and a confused conception of what constituted heart failure, has misled the physician in estimating its significance."

In phthisiology Auenbrugger's and Laennec's inventions have been even more abused than in cardiology. There is no doubt that without a physical examination of the chest no lesion in the deeper respiratory tract could be localized with any degree of reliability; to my mind even radiography cannot replace it satisfactorily. But one who makes a fetich of physical diagnosis, and relies exclusively on signs of slight alterations in the resonance of the chest and modifications in the breath sounds, is liable to prove more mischievous to his patients than one who knows nothing at all of percussion and auscultation. In the field of physical diagnosis my experience with medical men has proven the truth of the old dictum that a little knowledge is worse than sheer ignorance.

A physician with a smattering of physical diagnosis expects that every human being he examines must have a perfect chest; that no pathological changes should have occurred during the entire lifetime of the person. But this is as rare as a perfect man in other regards. For this reason perfect symmetry of the two sides of the chest, which would be required in a healthy man, is hardly ever encountered. There are anatomical causes, consistent with perfect health, why the resonance should be less pronounced and the breath sounds harsher, and perhaps the expiratory murmur more prolonged over the right apex than over the left. This is, in fact, found to be the case in a large proportion of quite healthy people. But when these persons cough because of some rhinopharyngeal catarrh, tonsillitis, etc., the uninitiated in physical diagnosis, the one whose perspective is rather narrow, finding the resonance slightly impaired, and the expiratory murmur somewhat prolonged over the upper lobe of the right lung, at once jumps to

the conclusion that he is dealing with a case of incipient tuberculosis. It is here that a physician, feeling that physical diagnosis is not one of his laudable attainments, will hardly ever fall into a diagnostic pitfall; the one who believes that he has mastered the mysteries of physical diagnosis to an extent that he can detect slight changes in the resonance and breath sounds of the chest promptly falls into a trap which may prove costly to his patient and to his own reputation.

These pitfalls may be avoided by bearing in mind the following maxims: Do not diagnose pulmonary tuberculosis merely because there are slight changes in the resonance of the chest, or alteration in the breath sounds heard on auscultation, unless the patient is troubled with constitutional symptoms of phthisis. If your patient has no fever his pulse rate is normal, and his cough may be attributed to some rhinopharyngeal condition which is clearly visible, you may disregard slight changes in the resonance and breath sounds, for the time being at least. You will only rarely fall into a diagnostic trap if you follow this rule. If you hear râles in the chest do not yet diagnose tuberculosis unless they are found exclusively over a circumscribed area in the lung apex. The more widespread over the chest they are audible, the less likely they are of tuberculous origin; when heard exclusively over one or both lower lobes, the chances of their being of tuberculous origin are very remote.

It is noteworthy that this fact is not appreciated, and we very often find physicians diagnosing tuberculosis of the lower lobes of the lungs in patients in whom the apices are free apparently from any pathological changes. The fact that the sputum in these cases, though abundant, is always free from tubercle bacilli does not matter very much to them; they are the "negative sputum" cases in sanatoriums where they are often kept for months and discharged "advanced" though perhaps improved.

These moist râles heard over the base of the lung indicate various nontuberculous processes. In those in whom they are found bilaterally they are due to primary or secondary bronchitis; though bilateral bronchiectasis is occasionally encountered. In most cases these coarse, moist râles are heard over only one base and they indicate bronchiectasis, nonspecific pulmonary infections, especially those following influenza, unresolved pneumonia, pulmonary abscess, chronic pleurisy, gangrene of the lung, and pulmonary infarction. When you find the upper lobes of the lungs free from signs of disease, you may make up your mind that you are not dealing with any tuberculous process; nor should you fear that the disease may turn into tuberculosis as some patients and, at times, physicians think.

The differentiation of these variegated diseases of the lower lobes of the lungs is very simple in most cass when several points are borne in mind: Chronic bronchitis is bilateral and is usually secondary to pulmonary emphysema, cardiac or renal disease. Examining the patient carefully, and discovering the primary disease, may save us from a diagnostic pitfall. Nonspecific pulmonary infections are unilateral, but here we have a history of influenza or pneumonia from which the patients had not recovered, but kept on coughing and expectorating material devoid of tubercle bacilli, despite its abundance. Always remember that it is exceedingly rare for tuberculosis to follow influenza or pneumonia. Moreover, despite the distressing cough and copious expectoration, there are few, if any, of the constitutional and toxic symptoms characteristic of advanced phthisis in which the lower lobes are involved. The temperature may be normal, excepting for acute exacerbations now and then when the bronchus communicating with the bronchiectatic cavity is clogged; the pulse rate may be normal—a phenomenon exceedingly rare in tuberculosis with signs of extensive involvement. In addition, there is a striking discordance between the symptoms and signs of disease on the one hand, and the general condition, especially the nutrition, of the patient on the other. Despite the severe cough and profuse expectoration, and the signs of large excavation in the lower lobe of one lung, he appears quite well nourished; he may even be gaining in weight.

In the uncommon cases of nonspecific pulmonary infections of the upper lobe, the diagnosis is not easy, and many mistakes are often made even by those who are most careful and experienced. Here only repeated examinations of the sputum decide.

Pulmonary abscess should never be mistaken for tuberculosis; but it is, as many physicians with hospital experience will attest. In pulmonary abscess we have a history of some preceding disease, especially pneumonia, influenza, etc.; of some pyemic process, as appendicitis, abscess of the liver, etc.; a surgical operation in which profound anesthesia was induced, especially tonsillectomy, or operations on the jaw in diabetic subjects. If the disease began soon after one of these diseases or surgical operations, the chances of its being tuberculous are negligible. Besides, the sputum is often fetid—rarely in phthisis, and no tubercle bacilli can be found. Gangrene of the lung is differentiated along similar lines. The extremely fetid and nauseating odor of the sputum, combined with the acuity of the symptoms, should render the diagnosis unmistakable. The sudden onset with pain in the chest, hemoptysis, etc., and a history and signs of the disease of the heart or blood vessels, especially phlebitis, should prevent the pitfall of pulmonary infarction being confused with tuberculosis in all cases in which the physician is only moderately careful.

Radiography has of late been extensively utilized in the diagnosis of the chest and many physicians rely on it almost to the exclusion of all other diagnostic methods. When the radiographer reports shadows or opacities on the plate, the patient is unhesitatingly pronounced tuberculous. There is no doubt that the Roentgen rays may supply information unavailable by other methods of diagnosis. No one appreciates this fact more than the writer who uses the *x*-rays in hospital and private practice almost daily, and who believes that while attempting to decipher the exact lesions in many of the advanced cases of tuberculosis, radiography has proved indispensable. But it is also a fact that in the diagnosis of early lesions in the lungs, and in the differentiation between active and inactive tuberculous lesions, radiography is only exceptionally of value. The main reliance is placed by radiographers on shadows, indicating airless lung tissue, or parenchyma converted into fibrous tissue or which has

become calcified. But airless tissue in the lung is not invariably due to tuberculosis; any change in the lung, pleura, hilus glands, and even in the skeleton of the thorax, of ancient or recent origin, will reveal itself on a good radiographic plate. These changes may be due to old disease processes which have healed long ago, but they do cast shadows on the plate which are the more pronounced the older the lesion and the more perfectly sclerosed or calcified it is. It is for this reason that radiographers who have never practised medicine, nor examined and followed up cases, not to mention those who have never attempted to verify their interpretations of plates with autopsy findings, report so often tuberculous disease in persons who are, and remain healthy.

It is clear that patients consult us with a view of finding out whether there is any disease requiring treatment; and tuberculous disease is a costly and tedious affair. They are no more interested whether there are any scars in the pleuræ or lungs, remnants of old and healed lesions, tuberculous and others, than they are interested in scars on their skins, the results of former injuries or disease. It does not matter to them to discover that at some past period of their existence there was an active inflammatory process, even if tuberculous in nature, in the chest which is now sclerosed or calcified. But it is just these changes in the thoracic viscera which radiography reveals best, and in many cases in which the radiogram shows a tuberculous lesion in an apex, that lesion has healed long ago and is of no more interest to the patient.

In many cases in which the radiogram shows opacities or shadows in the apices of the lungs we are in about the same position as when we hear a murmur in the cardiac region. Even when it is decided that the murmur is due to some defect in one of the valves; even when we find that the heart is hypertrophied, we do not invariably sound an alarm, instruct the patient to give up, or change the character of his occupation and institute rigorous rest treatment, unless there are symptoms of failure of compensation. It is dyspnea, pain in the chest, cyanosis, edema, enlarged liver, etc., that decide the course to be taken and not the murmur. Similarly in cases showing radiographic signs of lung lesions, even if beyond any doubt of tuberculous origin, it must first be determined whether the patient has any of the constitutional symptoms of phthisis before he is pronounced sick with this disease, before he is told to give up his life activities, separated from his family, prohibited from getting married, or banished to some distant clime or an institution. In other words, a patient who does not cough, expectorate, has no fever, night-sweats, emaciation, tachycardia, etc., is not sick with pulmonary tuberculosis, no matter what are the *x*-ray findings. For my part, I permit many of my patients showing undisputed signs of tuberculous cavitation in the lungs, both on physical examination and radiography of the chest, to continue at their avocations, if they are not of the hazardous types, as long as there are no constitutional symptoms of phthisis.

The pitfall of faultily interpreted radiography of the chest has swallowed many acute clinicians during the past eight or ten years. The result is that now you meet with many physicians of discrimination and experience who have lost the greater part of their faith in this diagnostic method. Too many patients who have been pronounced tuberculous by radiographers have kept up in good health without any treatment; numbers have gone through the hardships of warfare and returned healthier than before enlistment; too many lesions discovered by radiographers during the life of patients have been found either nonexistent or merely perfectly healed scars, when the lungs were removed from the chest after death and carefully examined. The result is that now the pendulum has swung rather too far in the other direction and many able and conscientious physicians are dispensing with radiography of the chest, which is again wrong. Taken in connection with the semiology of tuberculosis, and correlated with the subjective and objective symptoms and signs elicited by the clinician, the *x*-rays are undoubtedly valuable in the diagonis of tuberculosis.

We will now discuss the most important and, at the same time, the most nefarious of pitfalls in the diagnosis of tuberculosis. I refer to the determination of the activity of the disease. The patient calls on his physician for an opinion whether he is sick, not whether he has been infected with tubercle bacilli. Infection could be determined by any one merely by the application of a drop of tuberculin on the skin in the proper manner and it will be found that nearly every one would react. Even our army during the recent war did not attempt to decide whether the young men called to the colors had been infected with tubercle bacilli; no tuberculin test was used by the military surgeons.

And if the information our patients seek is whether they are sick and require treatment, every observant physician should be able to supply this information reliably. There is no acute need for any special training to qualify for this task. One need not be a virtuoso in physical diagnosis, nor a sharp in reading and interpreting plates to make a diagnosis of tuberculous disease of the lungs. The fact must never be lost sight of that a patient who does not cough, has no fever, has a normal pulse rate and maintains his body weight is, with but very few exceptions, not tuberculous; if you bear this maxim in mind, you will avoid one of the most common diagnostic pitfalls in the path of medical practice. If in your attempts at localization of a lesion in the lung in a patient who coughs, loses in weight, etc., you find that the apices are free from pathological changes, but that there are discoverable alterations in the resonance and breath sounds in the lower lobes, the case is, in all probabilities, nontuberculous in character. If you find râles over one or both lower lobes in such a case, the chances of the lesion being tuberculous are remote. If your patient spits blood despite the fact that he has no fever, tachycardia, etc., examine his nose and throat and you may find the source of the bleeding, but above all examine his heart, and inquire carefully into a history of rheumatism, and symptoms referable to cardiac disease, such as dyspnea, pain in the precordium, etc. If your patient's complaints are mainly dyspnea on slight exertion in addition to the cough and hemoptysis he, in all probability, suffers from heart disease and not from tubercu-

losis. In youthful individuals who cough and in whom one may find a fine tremor, dermography, flushed face, sweating of the hands which are cold, tuberculosis is very frequently diagnosed because in addition to these symptoms the patient is usually under weight and is easily fatigued. But it is always advisable to think of hyperthyroidism before banishing such a patient to Colorado, where he may do very badly.

While discussing the diagnostic pitfalls which are encountered on every step of the physician who attempts to decipher obscure diseases of the chest I have barely scratched the surface, but I cannot conclude without mentioning pulmonary tuberculosis in children of school age—a disease which is more often described in books and articles, and diagnosed by medical men, than really exists. I have seen some cases in children between eight and twelve years of age; very few in younger children, but on the whole it is exceedingly rare. Just contemplate the number of school children in any community, and then find out how many are admitted to sanatoriums for treatment and you will find that the proportion suffering from tuberculosis of the lungs is practically negligible. May I also whisper to you that even of the small number that is being cared for in institutions, clinics, and day camps, the vast majority never showed positive signs of tuberculous disease of the lungs; very few indeed have expectorated sputum in which tubercle bacilli were found.

Tuberculous tracheobronchial adenopathy, on the other hand, is very frequent. But no physician should frighten parents by the bogey of tuberculosis when he finds that a child has tuberculous glands in the chest. They are of no more significance than enlarged glands on the neck of children, tuberculous or others. To be sure, enlarged glands on the neck and within the chest are troublesome, but they are not deadly. It is indeed criminal to terrorize parents, to deprive children of an education, to separate them from their parents, because of signs of enlarged glands in the chest. Death due to this cause is as rare as death due to enlarged cervical glands. You may find now and then a case reported in a medical journal, but on the whole it is so rare that many experienced and wide-awake physicians have never encounterd one. Nearly all get well while continuing at school. You may recommend extra nourishment, a vacation in the country for a couple of months, administer some iodides, calcium, or cod liver oil, but by all means assure the parents that the child is in no danger worth mentioning.

170 West Fifty-ninth Street.

Neosalvarsan (Neoarsphenamine) in Yaws.—In Belgian Congo, West Africa, many of the natives suffer from frambesia. The head of the Mission of the Disciples of Christ located in that region, repeats that the results in the treatment of yaws by neosalvarsan were little short of a miracle to the natives who frequently go to the mission and ask for "the medicine of the needle." Dr. Pierson, the mission physician, says that most doctors there see from 200 to 400 cases of yaws in a year and that most of them when taken in the early stages, can be cured by a single injection of neosalvarsan, whereas if it were impossible to obtain the drug, the cases would go on to the tertiary stage, with all its suffering, and many of the unfortunates would be doomed for life.

SOME POINTS OF GENESIS AND DIAGNOSIS OF MENTAL DISEASES.*

By EMANUEL BRODSKY,

WESTPORT, CONN.

PSYCHIATRIST AND NEUROLOGIST TO THE ST. VINCENT HOSPITAL OF BRIDGEPORT, CONN.—CLINICAL DIRECTOR OF THE WESTPORT SANITARIUM, WESTPORT, CONN.—FORMERLY PHYSICIAN OF THE STATE PSYCHIATRIC INSTITUTION OF CANTON LUZERNE, SWITZERLAND.

The physicians of Connecticut commit about 1500 patients every year to the State Hospital for the Insane, and about as many are admitted voluntarily or are committed to the ten private institutions for the insane in this State. Until now, in most cases, the physician is required to testify only that the patient in question is insane. He is usually not able to determine what form of insanity the case represents or what the patient is suffering from. Such an unsatisfactory state of affairs is the result of insufficient facilities for clinical observation which are offered to the general practitioner.

However, we all recognize the importance of mental diseases as a public health problem. The United Public Health Service will soon expect the physician to make more definite diagnoses of mental disorders in order to be able to cooperate in the new program of mental hygiene. The new project was published in the Public Health Report issued Feb. 14, 1919. The United States Public Health service, in an effort to better the care and treatment of the insane, mental defectives, and the like, intends to enforce or secure: (1) the adoption of a model law providing for the early treatment of mental disorders, (2) the enactment of a model committment law, (3) the establishment of psychopathic pavilions in general hospitals, and (4) the adoption of a law making certain types of mental diseases reportable to the health authorities, etc.

The above mentioned problems and the interdependence of psychiatry with other branches of medicine make this paper interesting for the general practitioner. The points which will be brought out here may prove helpful in selecting cases of mental disorders which should be treated at home or in the psychiatric wards of the general hospitals. The importance of recognizing and selecting such cases will be understood when we turn our attention to the group of symptomatic psychoses and the group of psychoneuroses to which the so-called borderland cases belong. In the cases of the first group, *i. e.* the symptomatic psychoses, a day or even an hour wasted for formalities of commitment or transportation to a State institution is very frequently fatal to the patient. In the cases of the second group, the borderland cases, the commitment to a State or any other institution is sometimes undesirable, because the dissociation with his usual environment proves to be injurious to the future welfare of the patient.

To the group of symptomatic psychoses belong those mental disturbances which are the result of a distinct physical disorder. The mental disorders which are associated with distinct endocrinous disturbances or with distinct organic changes in the brain do not belong to this group. From the etiological standpoint we distinguish the exogenous

*Read in part before the Bridgeport Medical Society, May 6, 1919, in Bridgeport, Conn.

group and the endogenous group of symptomatic psychoses. The exogenous group comprises the symptomatic psychoses due to acute or chronic bacterial infection.

The symptomatic psychoses due to chronic bacterial infection are rare and are caused by the usual pus bacilli, the original seat being the teeth or the tonsils. We all know the relation of infected teeth to acute or chronic arthritis; in a similar manner the bacilli may, and do, reach other organs, such as the stomach, intestinal tract, gall-bladder, kidney, etc., and frequently, if not eliminated from these secondary foci, the removal of the infected teeth or tonsils will be of no avail.

Dr. Cotton of Trenton has published important observations on "Focal Infections in Mental Disorders" in the March, 1919, issue of the *Journal of Nervous and Mental Diseases.* The conclusions from this work are as follows: (1) chronic, masked, or focal infections play an important role in the etiology of the psychoses; (2) the origin of most chronic streptococcus infections is in blind alveolar or apical abscesses; (3) the organisms concerned in this infection spread from the teeth to other organs, notably the tonsils, stomach, duodenum, and lower intestinal tract, and these infections may persist even after the teeth have been extracted; (4) the organisms concerned in this focal infection belong to the short-chain or non-hemolytic streptococcus group; the *Staphylococcus aureus* and virulent colon bacilli are the most common in this type of infection; (5) the roentgenogram of the teeth often showed very little, if any, disease at the root, but the granuloma, surrounding the tooth just below the gum or between the roots of molars, was found to be filled with bacteria of the above mentioned type when cultured. The form of the psychoses due to chronic infections was the manic depressive type although they all had some aberrations from the classical cases of manic depressive insanity.

The acute symptomatic psychoses due to bacterial infections, *i. e.* the acute toxemias, are associated with or follow scarlet fever, typhoid, influenza, smallpox, malaria, and various other diseases. Only three infectious diseases do not produce such effects, namely, diphtheria, tetanus and tuberculosis, when they are not complicated or "crossed."

The chief characteristic of the mental disorders due to the acute toxemias are deliria with prevalence of visual hallucinations and confusion. There can occur different catatonic manifestations, convulsions, violence, suicidal tendencies with depressed or manic conditions. *The presence of visual hallucinations or illusions should always be considered either as an earmark of exhaustion or as a feature of more or less acute toxicosis.*

In time we may be able to differentiate the various forms of symptomatic psychoses from the etiological standpoint, but we lack, as yet, sufficient clinical material for it. However, we know that the delirium in smallpox is very intense and is accompanied by violence or suicide, while in typhoid it is attended more by manic excitement, and in malaria the delirium is very intense and takes place during the paroxysms. The deliria in septic processes are of a low muttering type and are accompanied by catatonic manifestations. The deliria which are observed in rheumatism develop either at the climax of the fever, or simultaneously with the subsiding of the swelling of the joints.

The endogenous group of the symptomatic psychoses represents autointoxications as the result of the disturbed function of the viscera. The chief characteristic of this group is the fact that the mental disturbances subside simultaneously with the improvement of the function of the affected viscera, or simultaneously with the elimination of those toxins which produce the autointoxication (as we see, for instance, in uremia). The chief representatives of this group are the mental disorders due to the disturbances of the function of the heart or kidney.

The mental disorders due to cardiac disturbances are of two types, namely, *the cardiac confusion and cardiac neurasthenia.* The *cardiac confusion* manifests itself through acute delirium, sometimes with violence and hallucinations or illusions of hearing and sight. The emotional condition is one of elation or mild fear with lacrymosity. This form of mental disturbance occurs in acute dilatation of the heart of any form of cardiac decompensation of acute origin. We all know that the approaching cardiac decompensation produces, as a rule, terrifying dreams and restlessness at night so that it serves us as a diagnostic point and a warning when we have a case of articular rheumatism or any other case, where cardiac complications are likely to arise. The acute confusions of cardiac origin subside sometimes in the course of 24 hours if proper measures are instituted. *The cardiac neurasthenia* is of a more chronic type and we may not discover any signs of decompensation or valvular involvement. The condition of the heart in these cases may be termed susceptible. The patients are clear, introspective, despondent, and experience a premonition of death; they cling to their people begging them not to leave them alone because they are "dying." Sometimes they are only irritable and complain of unpleasant sensations in the sterno-cardiac region. This condition may last several weeks or months and occurs mostly in younger individuals.

The mental disturbances due to the disturbed function of the kidneys, represent, besides those usual manifestations of coma, epileptiform convulsions and melancholic conditions, also certain fear conditions of acute character. The patients are terrified by their hallucinations or illusions of hearing or sight. Orientation remains partly if not completely preserved in all fields. The patients are in continuous fear and may commit suicide at the first opportunity. This mental disorder occurs during exacerbations in chronic nephritis where the specific gravity of the urine is not fixed.

It is clear that in these mental disorders of cardiac or renal origin proper measures should be instituted as soon as the diagnosis is made, and the treatment should be carried out in a psychopathic ward or under strict supervision at home.

Mental disturbances associated with diabetes are rare; they are, however, worth consideration. The picture is that of a melancholy process with ideas of self-accusation, auditory hallucinations, stupidity, and deterioration of habits. The patients improve simultaneously with the improving of the diabetic condition.

For a more detailed review of the symptomatic psychoses I can refer to my work published in the November, 1918, issue of the *Journal of Nervous and Mental Disease.*

Another important group of mental disorders which interests the general practitioner is the group of psychoneuroses, the so-called borderland cases. To them belong the obsessions and anxiety neuroses, mutism, and paralysis on a neurotic basis. The "shell shock" or war neurosis which was seen so often during the recent world war belongs to this class. The cases of neurasthenia or simple nerve exhaustion with its excessive fatigue—be it physical or mental—should be excluded from this group.

The genesis of this group will be understood if we analyze a few cases which came under my observation during the past few years.

CASE I.—A woman of 42 suffered from mysophobic ideas for a number of years. She was of Jewish faith, very intelligent, religious, and superstitious. During the six months before admission she developed an obsession which consisted in washing her hands according to a *certain code* before every meal and before going to bed. The code consisted in washing her fingers, wrists, forearms, and upperarms a number of times in such a complicated order that she would lose the sequence of the code and would be compelled to begin the process of washing her hands again and again. For this reason the washing would continue indefinitely, sometimes for 48 hours, and the patient would never be ready to feed herself or to go to bed of her own accord. She would scream every time she lost the continuity of the code, if compelled to go to bed or to take food when the hand washing was not completed. This condition became a menace to her own life and caused untold misery to her family. When compelled to go to bed without completing the hand washing she would not sleep and would hold her arms stretched out in such a manner that they could not touch the bed-covers. With the hands unwashed she would not touch anything in the house and compelled her nurse to burn or wash with soap and water those things which she touched by accident. There were no delusions of persecution nor did she manifest any evidence of hallucinations.

What does this process of handwashing represent? It undoubtedly represents an obsession. This obsession suggested new fear of contamination, which became so generalized that the patient began to consider every secretion and excretion from her body a menace to the outside world.

From analysis I found that she incorporated into the code of handwashing the number of the house in which she met her husband, the number of the house in which her marriage took place, her age, and date of her marriage. It was found that the woman had a personal conflict dating back to a meeting with a certain man. She "loved" that man for over 20 years but did not show her love to him. It was against her principles to be untrue to the man she had married. She always suppressed any thoughts or desires relative to the other man, *and in order to be more successful in combating this personal conflict she "unconsciously" established the above-mentioned code* which served her as a *"defense mechanism."* This defense mechanism "strengthened" her loyalty to her husband and satisfied her conscientious principles of morality. The code of washing the hands was abandoned as soon as the patient was told of the meaning of the figures she had incorporated in it and of the significance of the code as a defense mechanism; it required, however, a few weeks before the patient could again adjust herself to normal life. It is interesting to note here that a few months after apparent recovery the woman had a relapse of fear which was brought on by an attempt at sexual intercourse with her husband. Because mysophobia created ideas that her menses might be the source of contamination she demanded removal of her ovaries. This was done and the patient has been well since.

The woman revealed her personal conflict during the first examination when she said "my wedding cemetery" instead of "my wedding ceremony." She was not aware of the mistake until her attention was called to it. This mistake of speech—which at once reveals the tragedy of her life—indicates the importance of the function of the "subconscious mind."

While it is not my object to present a complete analysis of the case in this paper I wish to mention another mental mechanism of an obsession manifested by the same patient. When she was six years old she was strongly impressed when a girl in her class was punished for asking permission to leave the room during the hour. After this the patient used to vomit every morning before going to school. This lasted for about eight months until the patient's parents demanded that the teachers should not punish the children for such a request. However—although the patient ceased vomiting—she always, until she came under my care, suffered with difficulty in holding her urine and felt nauseated whenever she was in a crowd in a temple or theater. This is an example of an obsession as a reflex process through an association with a certain event.

CASE II.—A woman, 31 years of age, highly intelligent, married, has two children living. The history showed that the patient had been in a "delirious" state for ten days before she came under my care. During that "delirium" she would attempt to leave the house at any time during the day or night disregarding her personal appearance, clothing, and the temperature outdoors. She was taken to an institution where she was kept restrained in bed most of the time because of her tendency to fight violently when she was not allowed to leave the room during her "'delirious" states. It was thought that her condition was due to alcoholism.

A few minutes of examination showed that there was no "delirium" and that the patient never imbibed alcohol. The patient was in a continuous somnolent state from which she could be partially aroused. In the latter state she would converse very coherently but would fall asleep as soon as her attention was no longer absorbed. I instructed the nurse, who was with her all night, not to oppose the patient's attempt to get out of the room and informed her, also in the patient's presence, that the door would be locked on the outside. The patient attempted to open the door several times during the first night but always returned to her bed without any trouble. The following morning, in a half-somnolent state, the patient reported that she had dreamt during the night and that the same dream had recurred often during the past two years, although with some modifications.

The analysis showed that the dream was a wish fulfillment and that the persistent desire to leave the room occurred when certain events approached realization during the dream. Her moral obligation to her family did not allow her to compromise herself beyond a certain point even in her dreams.

In the first session the patient was told the meaning of the dream and the desire to leave the room during her somnolent states; she was told that she had a *personal conflict and that, as the result of that conflict, she had established a defense mechanism which prevented the realization of those desires which were repulsive to her moral principles.* The woman recovered after that session. The somnolent state together with the obsession to leave the room or the house never recurred.

This obsession represents a defense mechanism as the result of a conflict between the instincts of propagation and the sense of moral duty. Although the somnolent state was a medium of self-enjoyment, a basis for "dreams" from which she derived pleasure, yet she was compelled to leave the room every time the enjoyment began to transgress a certain limit. This compulsory action represented the obsession which served as a defense mechanism.

In this case institutional treatment was not imperative.

CASE III.—A man of 29 was picked up in the streets of Norwalk and brought to the Westport Sanitarium. He was a robust, healthy looking man, with normal expression and was slightly dazed. He did not know his name, his age, or his residence; said that he had walked from Willimantic and replied apparently relevantly to questions not concerning recent events. When asked to write his name he could copy it and could pronounce it when he saw it on a card which was found in his pocket. When asked about his name without the card he could not recall it. His physical condition was negative. For three days he remained in the same condition, not knowing where he came from, where he was, whether he was married or not, and whether he had children or not; but he conducted himself properly, enjoyed smoking his pipe, attended his meals, associated with others and conversed with them. Suddenly he "woke up", as he expressed himself, became perfectly oriented in every respect and requested writing paper for a letter to his wife.

This is a case of amnesia on a neurotic basis. It is similar to those cases of war neurosis which were seen so often during the recent war, when a soldier or officer would be found wandering some distance from his camp or from the battlefield not knowing his name or the regiment to which he belonged.

The psychic mechanism in this case and in the cases of war neurosis is similar. The history showed that the man was in great difficulties as the result of business. Penniless, and not being able to stand the pressure of the situation any longer or return home (his home was in New Haven), he relieved his mind through a compromise which expressed itself in amnesia.

CASE IV.—A man of 31 was suffering from an obsession of the following character: he was afraid to be near a high building or a tower; afraid to be in the street where there was a trolley track, a trolley car, or an automobile; he was afraid to be in a room in which there was a knife or an open window. The history showed that the man first experienced fear of being killed while working as a painter on the top of a high building. While working there he saw his mother passing by; he felt dizzy and was afraid that he was going to fall down. Since that time the patient had been afraid of everything which could remind him of a similar situation. Any high building, any tower (even though he himself was on the ground) produced fear. Furthermore, anything which could be associated with an accident or an injury produced a similar condition in him.

This is another example of an obsession as the result of an association with a certain event.

The conclusion which can be drawn from the analysis of the first three cases is the following: When the most important primitive instincts of man—the instinct of self-preservation and propagation—come in conflict with the ego of the patient or his personality, *i. e.* when a patient, being driven by those primitive instincts, comes in conflict with the laws and ethics of society, he develops a conflict which results in an above mentioned or a similar manifestation.

In Case IV and in Case I (when the patient suffered from nausea, vomiting, and inability to hold her urine while in a crowd) we have examples of an obsession which was evidently a reflex process through the association with a certain event. In the war neuroses the instinct of selfpreservation and the sense of duty created a conflict. *The neurosis is, therefore, either a defense mechanism against a conflict or a symbol of compromised satisfaction of a wish.*

Cases in civil life differ from war neuroses in that they are usually of longer standing and that the patient's resistance and, in most cases, the complexity of his mental mechanism is stronger developed.

It is possible that in all cases of psychoneurosis the mental mechanism is a complex reflex process. Mutism, amnesia, hysterical blindness, and paralysis are defense mechanisms of some reflex nature, but the solution of the problem is complete, there are no further compromises.

The obsessions which represent mental mechanisms similar to those we see in the code of washing the hands or in the necessity to leave the room, as presented above, are not complete solutions of the conflict. The patient continues to compromise himself, "subconsciously" building mechanisms which defend him from ideas which conflict with the ego and, at the same time, permit him to be influenced by the instinct of propagation.

Why should one patient dissolve the conflict completely and another partially? The answer to this might be found in the everyday experience. It is established that hysterical paralysis, mutism, deafness, amnesia, etc., occur in civil life among individuals who are less intellectual and on the battlefield among soldiers who are less qualified to be officers, while the qualified officer as well as the more intellectual element in civil life usually establish some kind of a defense mechanism in the form of an obsession. It is possible that the more intellectual type and the more qualified officer have a stronger sense of moral obligation towards their environment or superior officers and that this does not allow them to reveal their conflict. This factor, namely the sense of moral obligation, was understood and utilized in the treatment of these cases on the battlefields.

At the beginning of the war the patients suffering from war neuroses were immediately removed from the firing line and were sent to the interior of the country for treatment. It was soon established, however, that these cases were never cured. The procedure was then changed; the cases were treated and kept near the firing line or wherever the neurosis developed until it was eliminated. The patient was made to understand the causative factor—his primitive emotions—and was made to rationalize the ideas which were set up. In this way his discipline and his self-respect were taught to take command again.

In civil life the same holds true for a great many cases where the obsession is not very complex and not of very long standing. In my experience I have found it sufficient—in the majority of intelligent cases—to explain to the patient, after a thorough enquiry into his history, that the neurosis is an obsession as the result of a personal conflict and that the obsession is a defense mechanism against,

or a symbol of, that conflict. *The symbols appear equivalent to the desires but are usually transferred into a compromised satisfaction, a compromised wish fulfillment.* I also found that in obsessions of long standing the improvement did not follow immediately upon the solution of the conflict; it required a considerable period for his reeducation and readjustment to life.

Most cases of obsession, where there are no actual disturbances of the process of association, should be treated at home because it is important to keep the patient in contact with his environment. The patient who is mute, deaf, or paralyzed on a psychic basis often reaches the general hospital, but it is seldom necessary to place him in a psychiatric institution, because his recovery under proper treatment usually takes place before any such steps can be taken. These obsessions are frequently mistaken for real delusions of a melancholic condition or stereotypy of dementia præcox. A complete history and thorough acquaintance with the make-up of the patient will prevent such mistakes.

The Freudian theory gave us very important explanations as to the activity of the subconscious mind, but for the general practitioner it has no further value than to show what part mental mechanisms play in the formation of such obsessions. In every case we should obtain a complete history from the patient himself and should get acquainted with his mental makeup. If we are convinced that we deal with an obsession of this nature we should explain its meaning to the patient and, in general, its mental mechanism. The elaborate method of "catharsis," so much advocated by the Freudians, is superfluous in most cases, if not in all.

It is true that the patient must be able to understand the explanation of such mental mechanisms, and fortunately most of the neurotics who develop obsessions on the basis of such mental mechanisms are intelligent enough to understand—at least in a short period—the psychological basis of such formations.

In cases where the patient is not willing to cooperate with the physician it becomes necessary to apply a more extensive method of analysis and free association. This method evidently removes the distrust of the patient and reduces the modest feeling which plays part in the resistance. There are some other factors which prompt the patient not to cooperate with the physician but in most cases they may be disregarded.

The content of the dreams should not always be considered as a wish fulfillment. It is a realization of a compulsory thought, be it a wish for, or fear of, a certain event, *i. e.* the dream which is not of an accidental nature is the result of a thought which occupies the person's mind in a persistent or compulsory manner.

The brief consideration of these few borderland cases shows that a preventable disease is not always of bacterial origin. Much of our sick wastage is due to misdirected or dissociated thoughts. Although we know that neurotics are not made but are born, yet, we also know, that maladjustment is the cause of the above-mentioned manifestations, and if we direct the patient's mind and energy into the proper channels he will again become a useful unit in our society.

REFLEX PHENOMENA IN A RECENT SERIES OF INFLUENZA CASES.*

By SOLOMON GINSBURG, M.D.,

NEW YORK.

THE value of reflex phenomena as an aid in diagnosis was well known to the medical profession before James Mackenzie published his brilliant and fascinating work, "Symptoms and Their Interpretation." However, with the publication of this book, this genius of clinical medicine has helped considerably to stimulate greater interest in this most important subject.

At no time was I impressed as much with the great aid in diagnosis to be derived from a thorough study of reflex phenomena as during last year's pandemic of influenza. During the rush of the epidemic when vast numbers of patients were examined daily, among the unique clinical features of this disease two chief characteristics especially impressed themselves upon my mind in connection with the influenza cases that distinguished them from the ordinary cases of la grippe.

These two chief characteristics were:

(1) The almost constant presence of pleuropulmonary involvement in every case of pandemic influenza, no matter how mild the clinical course of the disease. (2) The almost invariable accompaniment of reflex phenomena in the neck, chest, abdomen, or back, whenever pleuropulmonary involvement was found on physical examination at some time during the course of the disease. It was striking indeed to find patient after patient, on the first day of the disease, complaining of reflex pain with no lung signs, later to develop pleuropulmonary signs in accordance with the reflex phenomena.

Many of the mild cases of influenza probably had never been examined by a physician, for the patients hardly considered themselves ill at all. If they did consult a physician it was more because of the scare of the "flu" than because they felt sufficiently ill to seek medical advice. Great was my surprise more than once to meet with these walking pneumonias, and to find an extensive pulmonary involvement in one lower lobe and a minor involvement on the other side in a patient who gave the appearance of almost perfect health. On careful questioning, however, these apparently mild cases would admit that, in addition to a slight cough, they had been suffering for some days with a sticking pain either in the neck, chest, abdomen, or back, which they would ascribe to a "touch" of rheumatism or a cold.

It was this frequent association of reflex phenomena, with pleuropulmonary involvement, which made me exceedingly wary in diagnosing myalgia, neuralgia, pleurodynia, or lumbago as a clinical entity even in the absence of definitely demonstrable disease in a viscus. And frequently on further watching of the case I was able to find the proof that a diseased viscus was responsible for the visceromotor and viscerosensory phenomena.

During the past few weeks in my private practice I have come across a series of cases, probably due to the attenuated virus of pandemic influenza,

*Read at a meeting of the Beth Israel Hospital Alumni Association, November 6, 1919.

which again show this frequent association of pleuropulmonary involvement and reflex phenomena. I therefore thought it of sufficient interest to record these cases, both because of their clinical value and for the warning they give of a possible recrudescence of great numbers of cases of influenza during the next few months.

CASE I.—P. D., aged 50 yrs., housewife. Previous history negative. On October 17, 1919, she suddenly developed severe aching pain in the left shoulder and scapular region, followed several hours later by a marked dull ache in the epigastrium radiating to the back. The pain was intensified on breathing and motion. She experienced slight nausea and dryness of the mouth, but there were no abdominal cramps, no chills, fever, or any other constitutional symptoms. On physical examination her temperature was 98.4° F., pulse 104, respirations 16. Throat slightly congested. Heart negative.

Lungs: At the left base showers of crepitant râles were present. There was no dulness on percussion, nor any change in vocal fremitus or resonance. The left trapezius showed hyperalgesia and there was tenderness in the left hypochondrium and in the epigastrium.

Diagnosis: Acute influenza, low pleural involvement including diaphragmatic portion of pleura, with a possible pulmonary involvement (capillary bronchitis).

CASE II.—A. G., aged 40 yrs., housewife, was suddenly taken ill with severe pain in the lumbar region most marked on the right side, very much aggravated on motion, hardly on breathing. Coincidently with this there were slight running of the nose, dryness of the throat, and slight prostration. On the fourth day after the onset of the illness, a slight cough and mucopurulent expectoration were present. Her highest temperature until the fifth day of her illness, when she was first seen by me, was 100.5° F., pulse 80.

On physical examination moderate tenderness was found to be present in the right hypochondriac region and in the right costovertebral angle. At the base of the right lower lobe numerous fine moist râles were present.

Diagnosis: Acute influenza with right pleurisy and bronchitis.

CASE III.—L. C., aged 43 years, ironworker. Has suffered from chronic bronchitis for several years. In August, 1919, he was treated for a cellulitis of the right index finger. A routine examination of his chest showed a moderate emphysema with numerous sibilant and sonorous râles and slightly prolonged expiration. On October 18 he consulted me at the office with the following history: One week ago he developed slight chilliness, fever, cough, mucopurulent expectoration, and pain in the left lumbar region. The pain was sharp and cutting in character, was not aggravated on coughing, deep breathing, or bending, but only on position: reclining in bed on the left side was very painful.

Physical examination showed no dyspnea, cyanosis, or prostration. Temperature 98.4° F.; pulse 72; respiration 24; heart negative. Lungs: Left chest posteriorly from angle of scapula down presented diminished breathing, showers of crepitant râles, and a few medium moist râles. There was no tenderness in the lumbar region, but the left trapesius was moderately hyperalgesic.

Diagnosis: Acute influenza, left pleurisy, including diaphragmatic portion of pleura and capillary bronchitis.

CASE IV.—M. G., aged 56 years, business man, has been suffering for 6 years from cough, mucopurulent expectoration, with many exacerbations and emissions, never any hemoptysis. Was never confined to bed for his respiratory condition. Since onset of "bronchitis," six years ago, he has had repeated attacks of left hemicrania, occurring every three weeks, and usually lasting a few days each time. During the past six months he began to have interscapular pain at night, only when lying in bed, or taking an afternoon nap. His present illness dates back to October 1, 1919, nineteen days before consulting me. At that time there was sudden onset with pain in the lumbar region and nocturnal urinary frequency, voiding at least three or four times at night. Slight weakness, nausea, poor appetite and headaches. No chills or fever.

Physical examination showed normal temperature; pulse 60; respiration 18.

His lungs showed moderate emphysema, and posteriorly over the left chest from the angle of the scapula down there were dulness, diminished breathing, numerous small moist râles and crepitations; at the right base a few moist râles were also present. He had pain on stooping forward and his left trapezius showed moderate hyperalgesia. His urine was negative on several examinations. Rectal examination and prostatic massage failed to show any prostatitis.

Diagnosis: Acute influenza, left-sided pleurisy, including the diaphragmatic portion of the pleura, capillary bronchitis.

CASE V.—I. K., aged 36 years, housewife, has been suffering from repeated attacks of bronchial asthma for the past four years. She was first seen on September 9, 1919, in a very severe attack of asthma; the ordinary sedative treatment not only failed to relieve her, but seemed to aggravate her condition. An autogenous vaccine containing *Staphylococcus albus* and *Streptococcus viridans* was prepared from her sputum, and injections were administered at five-day intervals. She seemed to improve nicely under the vaccine therapy. Physical examination on October 14 showed only an occasional dry râle and no prolonged expiration, although hyperresonance was still quite marked.

On October 22 she suddenly developed sticking pain in the left axillary, hypochondriac, and lumbar regions, aggravated on coughing, deep breathing, and lying on the affected side. Physical examination showed pleuritic crepitations in the left axilla. No asthmatic breathing and no moist râles. There was moderate tenderness along the left lower intercostals in the axillary region, and moderate tenderness and slight rigidity in the left hypochondrium.

Diagnosis: Acute influenza, left-sided pleurisy.

CASE VI.—P. M., aged 12 years, has both mitral and aortic valvular lesions with cardiac hypertrophy and dilatation and chronically enlarged liver, reaching about four fingers below the costal margin. She has been under my care since March 25, 1919, for slight myocardial insufficiency, which responded to digitalis therapy and general care. During the past few months she was able to attend school, was getting on fairly well in her class work, and could walk a distance of several blocks without dyspnea, and felt comparatively well. On October 17, 1919, she experienced slight malaise. Next morning there was loss of appetite. In the afternoon of the same day she suddenly stiffened out and began to scream at the top of her voice, "The world is coming down," "Father is going to Germany." For several minutes she kept repeating these words. She grew violent and would have jumped through the window if she had not been restrained. When she quieted down she had no distinct recollection of her behavior or utterances. A colleague, who was called, failed to find any pulmonary signs in her chest, and suspected gastrointestinal intoxication. When seen the next day, on the third day of her illness, she complained of slight sticking pain in her left axilla and slight cough.

On physical examination her temperature was 100° F.; pulse 104, slightly of the Corrigan type; respiration 20. Her throat was slightly congested. Her heart showed no acute condition except her old defects. The apex was found in the seventh interspace, anterior axillary line, one interspace further to the left than found six weeks ago. The lungs: In the left lower lobe from the angle of the scapula down there were showers of crepitant râles and a few medium moist râles. No hyperalgesia of muscles.

Diagnosis: Acute influenza, left side pleurisy, and bronchitis.

CASE VII.—C. H., aged 10 years, was first seen by me September 29, 1919, when she gave the following history: Two days ago she was suddenly taken ill with chilliness and fever. Cough and mucopurulent expectoration followed shortly after, and she experienced slight substernal pain on coughing. On physical examination her temperature was 100.2 F.; pulse 96; respiration 16. A careful examination of the lungs failed to show any abnormal physical signs.

The next day she was suddenly seized with a very severe pain in the lumbar region, so intense and excruciating that the child almost grew hysterical with the pain, and begged vehemently for quick medical relief. When I arrived one hour after the onset of the pain I met a colleague, who had been called in emergency, to relieve the intense pain. A physical examination of the lungs showed but a few dry râles scattered in both lungs, but no pleuropulmonary involvement. However, I diagnosed pleural involvement without being able to prove or localize the pleurisy, for I considered the pain to be due to a reflex visceromotor and viscerosensory phenomenon in the muscles of the erector spinæ group. When seen the next day a few fine, moist râles were discovered at the left base, but no pleuritic friction signs or dullness or diminished breathing. On October 5, six days after the attack of severe lumbar pain, the child was running a practically normal temperature for two days, although the dorsolumbar pain kept recurring, and was especially aggravated on coughing. Examination of her lungs now revealed on the left side posteriorly from the angle of the scapula down, dullness merging into flatness, distant bronchophony over a small area, pleuritic and medium moist râles. The left rectus and the left trapezius were neither tender nor rigid; the reflex was entirely confined to the muscles of the erector spinæ group.

Diagnosis: Acute influenza, pleurisy with a patch of bronchopneumonia.

Case VIII.—H. W., aged 26 years, lawyer, consulted me October 8, 1919, at my office. There was nothing in the past history that had any bearing on the present illness. She had been subject to attacks of "colds," but had never suffered a similar attack. On October 5 she suddenly developed a slight running of the nose and a slight sore throat with nausea, and once vomiting; slight chilliness, fever, and headache. The next day she suffered a fairly severe attack of pain, not cramp like, in the right side of the abdomen, aggravated on motion, hardly by respiration. A physician was called in to see her and diagnosed cholecystitis. When seen in the office, October 8, her chief complaints were cough, mucopurulent expectoration, and pain in the right side of the abdomen.

On physical examination her pulse was 76; respiration 18; temperature 99.4° F. Nose and throat congested; heart negative; lungs, diminished breathing at the right base, no râles, hardly any dullness. Abdominal examination showed marked tenderness in the right side down to McBurney's point; no enlargement of the liver, no palpable gall bladder. Urine negative. Right trapezius not tender.

October 13, five days later, patient was re-examined. The tenderness and rigidity were almost entirely gone. She coughed and expectorated less. There was still diminished breathing at the right base, but no râles.

Diagnosis: Acute influenza, right-sided pleurisy.

The correctness of the diagnosis may be questioned, but in view of the acute respiratory condition and in the light of the correspondence of this case with the above series of cases the diagnosis of pleurisy and not cholecystitis seems justifiable.

Case IX.—R. C., aged 58 years, gives a history of ureteral colic, high blood pressure, and hematuria once, six months ago. On October 23, 1919, she experienced malaise and weakness; next day there was a sudden onset of severe sticking pain in the left lower axilla, aggravated on motion and respiration; there were no chills, fever, or other constitutional symptoms. Two days later she developed severe pain in the following regions: retrosternal, right breast, right upper abdomen and right shoulder, intensified on breathing and accompanied by slight headache, chilliness, fever, and cough. The next day there was pain in the lumbar region.

Physical examination showed a moderately obese woman, no prostration, dyspnea, or cyanosis. Temperature 99.8° F.; pulse 80; respiration 20; blood pressure 240/110. Heart and aorta both enlarged. Lungs: an occasional fine râle at the right base.

Reflex phenomena: Moderate hyperalgesia of right trapezius, breast, pectoral muscles, scapular muscles, and upper rectus. Slight hyperalgesia of left breast, pectoral muscles, and upper rectus. There was moderate tenderness in both costovertebral regions. On re-examination October 28 she felt much improved, but there were numerous fine râles at the left base. Urine showed a trace of albumin, no casts, pus, or blood.

Diagnosis: Acute influenza, bilateral pleurisy.

Conclusion.—A number of cases probably due to the attenuated virus of pandemic influenza are here recorded, which present the following interesting clinical features:

1. The presence of pleural or pleuropulmonary involvement with relatively low temperature and very slight constitutional symptoms.

2. An almost constant presence of reflex visceromotor and viscerosensory phenomena in the neck, chest, abdomen, or back, which aroused the suspicion of pleuropulmonary involvement, entirely verified on careful physical examination at some time during the course of the disease.

1451 Prospect Avenue.

RADIOGRAPHY IN ARTIFICIAL PNEUMOPERITONEUM. *

By ALBERT S. HYMAN, M.D.,

DORCHESTER, MASS.

RESIDENT RADIOLOGIST, LONG ISLAND HOSPITAL, BOSTON, MASS.

The utilization of Kelling's discovery,[1] that gas introduced into the peritoneal cavity would render visible the contour and size of the solid abdominal viscera, has proved to be a valuable supplement to the usual radiologic examination of the gastrointestinal tract.

The opaque test meal is a simple and efficacious method of demonstrating the appearance of the inside of the hollow abdominal organs, but the roentgen ray tells us little or nothing about the outer aspect of these same organs or of the solid organs like the liver, spleen, gallbladder, kidneys, or uterus.

Jacobaeus[2] in 1910 and Rist and Maingot[3] in 1912 demonstrated the remarkable contrast effect produced whenever a solid body was radiographed in the presence of a gas under slightly increased pressure. The solid body apparently became more dense and the gaseous area more evanescent than when the two were radiographed separately. Experiments in artificially induced pneumothorax showed that this phenomenon held true for the human body and that radiographs of the chest showed cardiac shadows the more dense, the greater the degree of pneumothorax induced.

Ulrichs[4] in 1913 introduced oxygen gas into the peritoneal cavity and radiographed the liver and spleen of several subjects. Many doubted the wisdom of causing the patient to endure this uncertain procedure, although Godwin[5] in 1912 and Bainbridge[6] in 1913 both showed that oxygen could be injected into the peritoneal cavity for therapeutic reasons. Postoperative shock, peritonitis, and tuberculosis of the peritoneum seemed to respond to this type of "oxygen treatment."

The results of previous investigators apparently lay forgotten until 1918 when Goetze[7] described it as a new diagnostic procedure in radiology. Some-

*From the Radiologic Service of the Long Island Hospital.

what more recently the radiologic contrast phenomenon of gases and solid bodies has been used by Dandy[8] in demonstrating the cavities of the brain by injecting the spinal canal with air.

Stein and Stewart[9] in an excellent paper report their results in a score of cases and they voice their enthusiasm about the possibilities of this new adjunct in radiologic diagnosis.

The radiographic examination of the abdominal organs by the artificial pneumoperitoneum method has been a routine procedure at the Long Island Hospital for some time, and we believe that a brief report of our investigations will perhaps not be without value to others who are interested in this most recent of diagnostic methods.

Theoretically, the principal factor of the technique is simple. Oxygen gas is injected through a needle into the peritoneal cavity. Stein and Stewart describe their method as follows: After the patient is prepared in the usual way for roentgen examination he is put flat upon his back and the abdomen is inflated with from three to four liters of oxygen. The skin at the area of the insertion of the needle is painted with iodine and anesthetized by novocaine-adrenalin solution. The spot of choice is two to three fingers to the left of the umbilicus and about one and a half inches below it. The needle is pushed through until it touches the fascia. After a halt of a few seconds it is pushed through fascia, muscle, and peritoneum. The abdomen is inflated in from four to five minutes and about three liters of oxygen are introduced. The ordinary gas-oxygen anesthetizing apparatus is used; the oxygen is allowed to run into the mixing bag and is measured, and then it is forced through a rubber tube connected with the trocar.

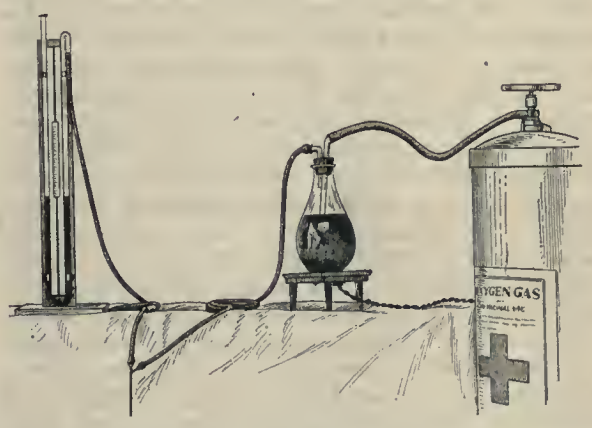
The authors report no bad results from this method, but we have not been so fortunate. The danger of injecting pathologic bacteria with the gas can not be over emphasized. Our first patients having shown a low grade peritonitis from which they slowly recovered, we undertook a rather elaborate bacteriologic investigation of the gas as it is supplied to hospitals in commercial tanks or cylinders. With the kind and able assistance of Dr. Katherine McCarthy of the Pathological Department of the Long Island Hospital, we were able to demonstrate the presence of staphylococci and streptococci in 60 per cent. of the various tanks that were examined.

Cultures of the gas coming from the rubber mixing bag of the nitrous oxide anesthetizing apparatus showed many colonies of *Staphylococcus aureus* and *albus* as well as many nonpathogens. A similar examination of two other rubber mixing bags which the hospital possesses demonstrated the same bacteriologic findings.

The obvious conclusion to be drawn from this work is that passing oxygen directly from a tank or from a rubber-mixing bag into the peritoneal cavity is not without some danger to the patient in that pathogenic bacteria may be introduced with the gas and a peritonitis of varying severity may develop.

The chief function of the gas-bag in Stein and Stewart's method is apparently to measure the quantity of gas injected into the abdominal cavity. They suggest the use of three to four liters of gas. In our experience, this has proved to be an unsatisfactory procedure, due undoubtedly to the great differences in the possible capacity of the peritoneal cavity in each patient. Some other device must be used if we wish all to receive a standardized amount of gas.

Intraabdominal pressure is easily measured by a water manometer. Normally, there is a negative pressure of about 25 mm. of water at the end of expiration and a positive pressure of 10 mm. at the end of inspiration[10]. If the patient strains vigorously the pressure will rise to 200 or 250 mm. Using this as the physiological maximum of intra-abdominal pressure we have found that the best results radiographically with the least discomfort to the patient have been obtained when oxygen gas has been injected until a pressure of 200 mm. has been reached. The quantity of gas may vary considerably with each patient. Small subjects will attain a pressure of 200 mm. with about one litre of gas, while large persons frequently require seven to eight litres of gas before 200 mm. is reached. We believe that this method is far more accurate and that the radiographs show richer contrast effects than when the gas is introduced by volume only.



Apparatus for inflating peritoneal cavity with warm, sterile oxygen gas for radiographic diagnosis.

A simple apparatus for the inflation of the peritoneal cavity with warm sterile oxygen gas is shown in the illustration below. The rubber tubing, side-arm trocar, flask, and glass tubes are made sterile by boiling; the nozzle of the outlet valve on the oxygen tank is made sterile with alcoholic solution. A sterile attendant then connects the oxygen tank to the filtering flask with a large-bore rubber tubing. The flask is two-thirds filled with hot liquid petrolatum and is in turn connected by rubber tubing to the trocar. A water manometer is attached to the side arm of the trocar. The petrolatum can be kept at boiling point, though not actually boiling, by an electric hot-plate or other heating device.

This superheated oil has a double function—first, it acts as a filter for those organisms that may be in the gas as it comes from the tank. An exceedingly short exposure to oil at this temperature (590° F.) is sufficient to coagulate bacterial protein. Secondly, the gas is warmed as it passes through the heated oil. Previous investigators have apparently overlooked the fact that as a gas is delivered from a tank it expands, and this expansion is accompanied by

a remarkable lowering of the temperature according to well-known gas laws. The frozen section apparatus of the pathologic laboratory is based upon this principle. We have found that the temerature of the oxygen gas coming from a compressed tank through 30 inches of rubber tubing averages about 27° F. in a series of ten experiments performed in order to determine this point.

So far as we have been able to discover, there has been no direct experimental work showing the effect produced by injecting very cold gases into the peritoneal cavity, but if one can remember that exposure of the peritoneum and intestines to the air at room temperature during operation is conducive to post-operative shock, then there seems to be no doubt but that a pneumoperitoneum produced by an icy cold gas would cause the patient a tremendous amount of shock and possibly collapse.

The oxygen gas as it emerges from the trocar of the apparatus above has been found to be sterile on repeated bacteriologic examination. The temperature of the gas will vary from 95° to 110° F. Together with the water manometer we believe this apparatus to be the safest and simplest method of injecting a standardized amount of gas into the peritoneal cavity for diagnostic purposes.

When the desired pressure has been reached, the trocar is removed and the small wound is covered with a bit of sterile cotton soaked in collodion. After resting for a few moments upon his back, the patient is instructed to take the knee-chest position for about 15 or 20 minutes. This manipulation allows the gas to rise into the pelvis and removes the peculiar but not particularly unpleasant sensation which most patients feel in their shoulders and back, due apparently to pressure on the dome of the diaphragm from the gas. (Compare, for example, pain from the gallbladder localized in the right shoulder.) The patient then lies in the prone position for about one-half hour longer in order to allow the gas to pass behind the liver, spleen, and stomach. Examination by fluoroscope and radiograph can now be made. The oxygen is usually entirely absorbed at the end of 24 hours.

It is interesting, at this time, to note that Rosenblatt,[4] working with a pneumothorax apparatus, accidentally produced a pneumoperitoneum by injecting air below the diaphragm. Radiographs taken of the patient showed shadows of the liver and spleen. This invites the question as to whether air can be substituted for oxygen and still be as innocuous as the latter. Further work is needed along this direction.

Artificial pneumoperitoneum for radiologic diagnosis is indicated in all obscure conditions concerned with the liver, spleen, stomach, kidneys, and uterus. The size, shape, and relations of these organs can be demonstrated with surprising exactness. Occasionally, the gallbladder and sigmoid are seen.

Perhaps the condition, *par excellence*, for this method of diagnosis lies in that group of cases complicated by ascites. Examination of the liver and spleen in these cases is usually impossible, yet the diagnosis depends for the most part upon what these same organs can demonstrate. The method becomes exceedingly simple here, for an abdominal paracentesis having been performed to remove the ascitic fluid, oxygen can be introduced through the same needle and radiographs taken without causing the patient the slightest additional discomfort. Therapeutically, also, artificial pneumoperitoneum is indicated in these cases; many patients suffer from disturbances of circulation with vertigo, nausea, syncope, and the like upon sudden removal of pressure from their large abdominal vessels. The introduction of gas under pressure tends to reduce these ill effects, and as it is absorbed in 24 hours it allows the change to occur more slowly and with far less distress to the patient.

From *a priori* reasoning, one might imagine that artificial pneumoperitoneum combined with the opaque test meal would give a remarkable radiographic presentation of the gastrointestinal tract and the solid organs at the same time. Our results with the combined methods have been disappointing. Increasing intraabdominal pressure apparently disturbs the motor activity of the alimentary canal so that radiographs of the stomach and intestines are usually very poor in detail. This may also be the explanation of the unsatisfactory results of barium studies in cases of ascites, although the prevailing theory seems to consider the presence of fluid in the abdominal cavity as the chief cause of poor pictures.

We believe that a more accurate radiologic diagnosis can be made when the two methods are used separately. For this reason, the procedure which we have developed at the Long Island Hospital for the diagnosis of intraabdominal conditions is as follows: Patients are prepared for barium studies by having their alimentary tract thoroughly cleansed by catharsis and enemata twenty-four hours preceding the examination. Only liquids are given the night before. At 9 A. M. a barium test meal is given and a sufficient number of fluoroscopies and radiographs are done for the next twenty-four hours as are necessary to make a diagnosis. The patient is given active catharsis on the second day to expel any remaining barium and on the following morning he receives his oxygen inflation. Radiologic examination is again made. The two sets of plates are then carefully reviewed together. One is frequently astonished how much one set of plates will supplement the other.

While we do not advocate that every gastrointestinal study should receive a pneumoperitoneum diagnosis, yet in view of the simplicity and safeness of the method, we believe that it should be adopted as a supplementary mode of diagnosis in all cases where the test meal does not demonstrate the condition accurately enough to reveal the cause of the symptoms, and we especially recommend the method for the study of the pathologic conditions of the liver, spleen, and kidneys.

COMMUNITY HEALTH UNITS AND HEALTH INSURANCE.

By A. C. BURNHAM, M.D.

NEW YORK.

THE New York County Medical Society, in a recent meeting, placed itself on record as almost unanimously opposed to Compulsory Health Insurance. At the election for president of the society the successful candidate stated his views as follows: "I am emphatically opposed to Compulsory Health Insurance, and to all the impracticable forms of paternalism that have seized upon the minds of some of the erratic advanced thinkers of the present day."

Curiously enough, the same mail which contained the letter setting forth the views of the candidate also brought an appeal for a donation to the United Hospital Fund, stating that the hospitals were in desperate need of funds for the care of the sick. On the same day the *Journal of the American Medical Association* (November 22, 1919) contained the following editorial comment: "The question of obtaining efficient medical diagnosis and treatment for cases of obscure disease is one of the live questions of the day. It is doubtful whether it can be met by diagnostic clinics unless they are heavily subsidized organizations along the lines of existing dispensaries but differing from them in the fact that a small fee is charged. Attempts have been made to meet the situation in this way, but as yet there has been no widespread effort to care for the man of moderate means. As individuals of this group furnish the great bulk of patients, some machinery must be devised which will enable them to have inexpensive but adequate care when they develop obscure diseases."

Is it any wonder that the average physician is puzzled and undecided in his attitude toward any form of Health Insurance? On the one hand we are told that sickness is broadcast and that the man in moderate circumstances is not receiving proper medical care, and on the other hand we find some of our best medical men putting themselves on record as opposed to the one plan that has been brought forward for the relief of the present situation.

It does not speak well for the medical profession that among innumerable letters received opposing Health Insurance not one contained a word regarding any measure which might overcome the evils which Health Insurance attempts to remedy. For there can be no doubt that the evils do exist, and that, owing to the complexity of modern practice and with the tendency toward specialization, the problem of securing adequate medical care is becoming more and more difficult for the family in moderate circumstances. The inadequacy of medical treatment is emphasized by the report on Social Insurance issued by the American Medical Association (Social Insurance. Report of the Special Committee of the American Medical Association. Social Insurance Series, Pamphlet XI, 1919), which says on page 45: "All sickness surveys show a considerable number of sick persons who receive no medical attention at all, or receive it too late to prevent the illness from becoming serious." They found that in six surveys covering 13,000 seriously ill persons, 30 per cent. were having no medical care. In the Chelsea District, New York City, there were among 356 sick persons no less than 38 per cent. who were not under the care of a physician.

In speaking of dispensary treatment, the report says: "Perhaps the most serious feature of our large dispensary population is that of delayed treatment. Of 1,726 dispensary patients studied in Boston, 72 per cent. had had no previous medical care. Of these, 35 per cent. had been sick for more than three months."

If this situation exists, and there can be no doubt that it does exist, it behooves the medical profession to bestir itself and to present a workable plan for the care of the large number of seriously ill, who at present are receiving no treatment or inadequate medical attention, instead of leaving the whole question to organized charity, or, what is worse, to unorganized financial and medical aid which are often both inefficient and ineffectual.

Much has been done and will continue to be done by the community for the relief of sickness in spite of a certain amount of opposition by the medical profession. The excellent work which has been done by the New York City Board of Health in the control of infectious diseases, including pulmonary tuberculosis, may be cited as an example of what may be done by community effort properly controlled. Similar health control is undertaken by the New York State Department of Health, with equally satisfactory results. However, the writer has more than once heard the Board of Health condemned because of what is considered a trespass on private practice and upon the rights of the individual.

In the presentation of the following plan for Community Health Units the author disclaims any credit for originality. The system as suggested is based upon what has come recently to be known as "group medicine," and has been familiar to medical men for a long time in dispensary and hospital practice, modified to meet the demands which will be made upon the physician by the Health Insurance Act and modeled somewhat along the lines followed by the Department of Health in the care of tuberculosis.

The Health Insurance Act provides that the insured shall receive medical and surgical care and that funds shall be provided for proper laboratory and other facilities for diagnosis and treatment.

How may this best be secured for a given community with least expense and greatest benefit to the patient?

Given a group of, let us say, ten thousand insured in the same community, how many we best secure adequate medical and surgical treatment, including laboratory and hospital facilities? Leaving out of the question entirely the income of the physician, there can be no doubt that for such a community the most efficient services could be secured by means of a definite group of individuals working somewhat on the plan of a group clinic or dispensary. The physicians would be paid a salary according to the time devoted to the work and the experience of the physician.

As a tentative plan for such a unit the following division might be made of the personnel: 1 Medical consultant (part time); 1 surgeon (part time); 1 assistant surgeon (part time); 1 eye, ear, nose, and throat surgeon (part time); 1 gynecologist (part time); 1 neurologist (part time); 1 pathologist (part time); 1 obstetrician (part time); 1 dentist (full time); 5 visiting physicians (full time); 5 visiting nurses (full time); 1 chief clerk (full time); 3 assistant clerks (full time); 1 laboratory technician (full time); 1 *x*-ray technician (full time).

It is believed that such a working force could give all care contemplated in the Health Insurance Bill to a community of 10,000 persons located in a city, or in a closely settled suburban district where the calls could be made without too great a loss of time. It is estimated that in New York City such a clinic could be run for approximately $50,000 yearly, including salaries, rent and incidentals, or $5 per insured person. It is understood, of course, that many of the more seriously ill would be taken care of in the hospitals, and that the group could be enlarged or contracted in case of epidemic or during any period when the medical work was especially heavy. If found desirable the *x*-ray work and laboratory examinations might be made more conveniently at a nearby hospital. This would probably be cheaper and more satisfactory in every way.

How many persons would be treated by such a clinic? In a health survey made in Farmingham, Mass., it was found that among 6,582 persons 407 were ill, a sickness rate of about 6 per cent. This would mean that in 10,000 persons there would be approximately 600 sick all the time. Of this number about one-half would be unable to work and from 10 to 20 per cent. of all cases sick would be sick in bed. It seems fair to presume that the average number of house visits would not be more than ten to fifteen a day for each of the five general practitioners. These figures, of course, are not definite, but it is believed that they represent fairly closely what ought to be expected.

Could the better type of physician be secured for this work? Would he be willing to devote his entire time to work of this sort? I believe he would if the service was arranged so that the physician was paid a living wage during the time he spent as a full-time physician and promotion was so arranged as to offer him a career as a health officer. The hours of duty and type of work done must be so arranged that the physician in the course of his work is encouraged to specialize just as he is in the army. He would be assigned to duty with one of the specialists during the clinic hours, and would naturally drift toward that specialty. After a comparatively few years he would be qualified as a specialist and promoted to a position as consultant when a vacancy occurs, and then placed on part-time duty. This would enable him to develop a private practice in addition to his work in the Health Unit and his position would be much the same as the specialist who, in addition to his practice, devotes a large part of his time to hospital and dispensary practice.

It has been stated that Health Insurance will do away with private practice and the development of scientific medicine. This is not true. Indeed, the result has been directly the opposite in countries which have adopted health insurance. The well-to-do continue to employ the best medical advice obtainable regardless of expense, while the unemployed continue to depend on charity. The medical schools and colleges continue to attract the best type of medical skill, even at comparatively low salaries, just as they do in this country. The physician practising under Health Insurance will have as much chance of a career as at the present time. The physician is in the largest sense of the word a public officer. He has his obligation to the community and to the individual. If he is not ready and willing to serve the community he should not be permitted to practise medicine. If he does not give to the individual the best that modern practice prescribes, he is unfair to the patient. If he serves them both to the best of his ability he also serves himself.

How would an individual case be cared for by such a scheme? Let us suppose a case of acute bronchitis occurs. The clinic is notified and word is sent by telephone or otherwise to one of the visiting physicians who is then on duty. (In the case of night calls one physician would be designated who would be on call for emergencies on that particular night.) The physician visits the case and prescribes treatment. He then notifies the visiting nurse, who makes up the clinical record and sees that the physician's orders are properly carried out. If the patient is desperately ill the medical consultant may be asked to see the patient, and, if necessary, hospital treatment may be advised or laboratory examination secured. In an uncomplicated case the physician makes daily visits while the man is seriously ill, but during convalescence visits are made chiefly by the visiting nurse, who makes periodical reports as to his condition. When ready to return to work he reports at the clinic for a final examination.

Free choice of physicians is the chief obstacle to a plan of treatment such as outlined above. It is supposed to be the inherent right of a patient to pick his own physician. Just why this is true, when he is not allowed to pick his instructor in school or his professor in college is difficult to understand. When a man is admitted to the average New York hospital he is assigned to a certain ward and seldom has anything to say about free choice. In the army and navy there has never been any free choice, and on the whole the medical service is excellent and the patients are entirely satisfied. Free choice of

physicians and efficient service cannot be combined to give adequate medical treatment at a low price.

In presenting the above outline the writer has attempted to present only a tentative plan in order to invite discussion along the general lines of group treatment. The plan is in accordance with what has already been accomplished in group dispensaries and diagnostic clinics, and is in keeping with the modern trend of scientific medicine and social welfare.

Since the above article was written the *Journal of the American Medical Association* (November 29, 1919) has referred editorially to a similar plan to be carried out in Glasgow. The experiment proposes the institution of "a complete medical service, furnishing unrestricted treatment of every citizen needing it, and involving the enrollment of the medical profession and the public control of all general hospitals and infirmaries."

In reference to the free choice of physicians the *Journal* says, in part: "An interesting side light is thrown on the provision for free choice of physicians under the social insurance plan now in operation. A careful study of the district shows that since the introduction of social insurance and the panel system in Glasgow those affected have not made an effort to exercise any choice in the selection of physicians but have gone to the nearest and most conveniently located physician."

THE LEGISLATIVE HISTORY OF COMPULSORY HEALTH INSURANCE IN THE STATE OF NEW YORK.*

By JOHN P. DAVIN, M.D.,
NEW YORK.

The first bill for compulsory health insurance in New York State was defeated at the 1916 session of the Legislature. In 1917 it was reintroduced. As the representative of the Medical Society of the County of New York I was delegated to oppose this measure, not only in practice, but in principle. I also opposed the plan for a commission to study and report upon it, and for any appropriation of public funds for this purpose. At this session the manufacturers, the labor unions and the great commercial organizations were also represented in opposition; in fact, Capital, Labor, and Medicine were as one in opposing compulsory health insurance.

What then was the power behind this measure? It was the so-called "Uplift" or "Social Service," a movement which I described in the following words taken from an article on "Adolescent Insanity and the National Health," by Professor Charles W. Burr of the University of Pennsylvania:

> The kind of altruism which is being widely preached in America at the present time is making life much easier for a great many lazy people, but which, instead of improving the race, is injuring it. In too many instances it is aiding people to live whom it were better to allow to die. It forgets too often that the strong and healthy also have rights. Its honest adherents are so ruled by their emotions, or rather by their sensations, that they do not stop to think before they act. They see an evil and in their hurry to correct it inflict much greater evils. It increases tremendously the parasitic class who to-day, as always, are perfectly willing to live off the fruits of other people's industry. The specific movement, technically called "social service," the result of a genuine spirit of altruism, needs a little reform in its methods and a somewhat greater care in the choice of its agents, or its possible usefulness will be greatly diminished. The idea that a man is his brother's keeper is a beautiful and normal thought, but when it is interpreted to mean that the strong man is to be "wet nurse" to the weakling, and carry him through life, and work that he, without exertion, may enjoy the luxury of living, the weakling is going to enjoy himself without responsibility, propagate his kind, and weaken the race. No work needs greater wisdom and maturity of mind than social service, yet far too often its agents are enthusiastic, ignorant, and conceited young men and maidens, who, feeling that they have a call to save the world, entertain unlimited pity for the unfortunate, an overwhelming sense of the wickedness of the strong and successful, have no idea of justice, no training of any kind, little or no worldly wisdom, but, also, not unfrequently a desire to earn a living without hard work.

Even at that time I discerned the political possibilities that lay within this form of legislation, and declared it to be a fight to a finish between practical politics and the practice of medicine, adding at the same time that when politics began to tinker with life and death it was time to call a halt.

Compulsory health insurance, I told the Legislature was the most ambitious medical proposition that had been advanced since Colonel Sellers first offered his internal, external, and eternal remedy for human ills. In advocating this promotion Dr. Warren of the Public Health Service computed that there was something like a billion in it for the doctors, whereas Colonel Sellers only claimed for his remedy a matter of some millions in it for his dupes.

On the other hand, but for the limitless wealth of the public treasury and for the modern craze for lay interference with the care of the sick, a measure such as this one would not receive serious consideration anywhere outside of an economic Bedlam.

Although the bill was defeated, a commission was appointed to study the subject and report upon it. No appropriation was granted, however, for this purpose, although this largess was favored by all the opposing interests except the one I represented. At the next session of the Legislature, labor had changed its front, and favored this measure. The other opposing forces were divided, and politics began to take a hand in the project. The chief spokesman for the measure was an official of the State Industrial Commission, a body largely under the control of the State Federation of Labor, and the one under which this law would be administered if it were passed. It was admitted by this official that his body had spent a hundred thousand dollars in investigating this subject, although an appropriation for this purpose had been refused at the previous session of the Legislature. Again this measure failed to pass the Legislature.

Representing then an independent medical organization, I again appeared in opposition at the 1919 session of the Legislature. At this time I concentrated my attack upon what I considered the most formidable body among our opponents, the labor unions. It was my opinion that if they succeeded in getting the medical profession under their control they would change our working day even of twenty-four hours when necessary into one of eight hours, while the time of an epidemic would be the

*An address delivered by invitation at an informal meeting of the Medical Society of the State of New Jersey, held in Newark, on January 6, 1920.

one in which they would be most likely to call us out on strike. It was no disgrace, I averred, for labor to work for its pocket all the time, but if they applied this rule to us it would be against all the established principles of our once honored profession.

Owing to the determined stand of one man, the speaker of the Assembly, who prevented this bill from coming out of committee, this measure again failed, against the united efforts of the Governor and of both parties in the Legislature.

We are now confronted with the declared intention of Governor Smith, backed by the State Federation of Labor, and by the political advocates of so-called welfare legislation in both parties, to pass a measure for compulsory health insurance at the next session of the Legislature. In this determination Governor Smith seems anxious to emulate Bismarck and Lloyd George in making the medical profession in this country an adjunct of the State under political control instead of an independent vocation such as it has been up to the present time. As such, unaided by the State, medicine has exerted a beneficent influence in the affairs of mankind which has more than equaled the individual achievements of politics, jurisprudence, and industry, so far as they relate to the welfare of mankind in general.

What is there in the history of politics in New York State to justify the project for making the practice of medicine subservient to the politician, and a public instead of a private duty? Has it ever been proved that medical service to the poor was either insufficient or inefficient? Is there any complaint even to-day of the high cost of medical attention to the people? Has Governor Smith as a poor boy brought up in New York any proof of a lack of medical service to the poor at any time during his career among them? It has been said that taxes and death are inescapable obligations of mankind. At the present time we have the highest tax rate and the lowest death rate ever recorded in the history of New York.

The levying of taxes is the duty of politics; the delaying of death the responsibility of the physician. Does any one imagine that the expectation of life would be increased if politics assumed both of these duties at the present time? To-day the medical profession in New York State is unanimously opposed, to compulsory health insurance with the single important exception which proves the rule. This one exception is the president of the American Medical Association, who has recently declared that we should remember in our opposition to compulsory health insurance that we are only 15,000 among 8,000,000 in New York. In this respect it may be said that he is only one among 15,000, no matter how high placed he may be. I have advised at the present time that the medical profession of New York refrain from again appearing in opposition to compulsory health insurance at the hearing before the Legislature at its coming session, but that we should register instead our unanimous opposition to it before the Governor and this body.

We have just seen two parties to a trade dispute summoned to the Capitol at Albany to arrange their difficulties. This dispute is among the highest paid form of labor, the needle workers, who number 90,000 and who vote as their interest dictates. These workers are treated with a respect that has never been given to the medical profession, the most charitably inclined, the most poorly paid, and the least influential class politically in the country. Is it not high time for us to act with the unanimity of the ladies' tailors, 98 per cent. of the members of which trade were declared some years ago by a Federal health survey to be diseased. Either this diagnosis was wrong or the diseases from which this trade then suffered were those which money could cure.

The medical profession of New Jersey is to be congratulated upon the unanimity with which it is opposing the first measure for compulsory health insurance in their State. In this opposition to "an act to promote conservation of human life by creating a bureau of health insurance in the Department of Labor," New York wishes them every success in their initial contest with the forces we have met and defeated four times, and which we are again to meet for the final struggle this year.

117 West Seventy-sixth Street.

LAPSUS OF MEMORY.

By H. LAVESON, M.D.,

NEW YORK.

Freud has shown in his "Psychopathology of Everyday Life" that we tend to forget the things that are displeasing to us, that unconsciously we avoid what has once caused us pain. The objection has been raised to this theory that as a matter of fact it is the painful things that we never forget, and that these impress themselves most on us. Such critics might have taken it for granted that the scientist who laid down the principles that the nemoses which date from the earliest painful love experiences which are never forgotten, but merely repressed and unconscious, would not have overlooked their objections. Certainly we do not forget painful things, but nature has so provided that we have a tendency to repress into our unconscious annoying events and go on our way as if they had never happened, only in symptomatic acts, mistakes, slips of the tongue, and otherwise do we betray ourselves. The man whose wife has lied never forgets it if he has loved her. But if he has, let us say, been slighted by a person who has not been playing a principal part in his life, he will go on living as if that person had never existed for him. He may unconsciously avoid the street where that man lives, and forget about him, until some occasion may arise where he may betray his dislike of the person in a manner he never intended; the action is nevertheless, the voice of his unconscious. Analysis of name forgetting almost always shows that the name withheld shows some relation to a theme which concerns one's own person, and is apt to provoke in one strong and often painful emotions. The same thing might be expressed in the following form: The name withheld has touched a "personal complex." The relation of the name to my person is an unexpected one and is mostly brought about through superficial associations (words of double meaning and of similar sounds); it may generally be designated as a side association. The mech-

anism of forgetting, or rather of losing or temporary forgetting of a name consists in the disturbance of the intended reproduction of the name through a strange stream of thought unconscious at the time. Between the disturbed name and the disturbing complex there exists a connection either from the beginning or such a connection has been formed—perhaps by artificial means—through superficial association. The self reference complex proves to be the most effective of the disturbing complexes.

To avoid the wakening of pain through memory is one of the objects among the motives of these disturbances. In general one may distinguish two principal cases of name forgetting; when the name itself touches something unpleasant, or when it is brought into connection with other associations which are influenced by such effects. The mechanism similar to that pointed out in the forgetting of names may also play a part in the phenomena of speech—blunders. The speech disturbance which manifests itself as a speech-blunder may in the first place be caused by the influence of another component of the same speech, that is, through a fore-sound or an echo, or through another meaning within the sentence or context which differs from that which the speaker wishes to utter. In the second place, however, the disturbance could be brought about through influences outside this word, sentence, or context, from elements which we did not intend to express, and of whose incitement we became conscious only through the disturbance.

No psychological theory has yet been able to account for the connection between the fundamental p henomena of remembering and forgetting; indeed, even the complete analysis of that which one can actually observe has as yet scarcely been grasped. To-day forgetting has perhaps grown more puzzling than remembering, especially since we have learned from the study of dreams and pathological states that even what for a long time we believed forgotten may suddenly return to consciousness.

No other group of phenomena is better qualified to demonstrate the thesis that lack of attention does not in itself suffice to explain faulty acts, as the forgetting of intentions. An intention is an impulse for an action which has already found approbation, but whose execution is postponed for a suitable occasion. Now, in the interval thus created sufficient change may take place in the motive to prevent the intention from coming to execution. It is not, however, forgotten, it is simply revised and omitted.

We are naturally not in the habit of explaining the forgetting of intentions which we daily experience in every possible situation as being due to a recent change in the adjustment of motives. We generally leave it unexplained, or we seek a psychological explanation in the assumption that at the time of execution the required attention for the action, which was an indispensable condition for the occurrence of the intention, and was then at the disposal of the same action, no longer exists. Observations of our normal behavior toward intentions urge us to reject this tentative explanation as arbitrary. If I resolve in the morning to carry out a certain intention in the evening, I may be reminded of it several times in the course of the day, but it is not at all necessary that it should become conscious throughout the day, as the time for its execution approaches it suddenly occurs to me and induces me to make the necessary preparation for the intended action. If I go walking and take a letter with me to be posted, it is not at all necessary that I, as a normal not nervous individual, should carry it in my hand and continually look for a letter box. As a matter of fact I am accustomed to put it in my pocket and give my thoughts free rein on my way, feeling confident that the first letter box will attract my attention and cause me to put my hand in my pocket and draw out the letter. This normal behavior in a formed intention corresponds with the experimentally produced conduct of persons who are under a so-called "past-hypnotic suggestion" to perform something after a certain time. We are accustomed to describe the phenomenon in the following manner: the suggested intention slumbers in the person concerned until the time for its execution approaches. Then it awakes and excites the action.

We have invariably found that intentions of some importance are forgotten when obscure motives arise to disturb them. In still less important intentions we find a second mechanism of forgetting. Here a counter-will becomes transferred to the resolution from something else after an external association has been formed between the latter and the content of the resolution. Errors of memory are distinguished from forgetting and false recollections through one feature only, namely, that the error (false recollection) is not recognized as such but finds credence. However, the use of the expression "error" seems to depend on still another condition. We speak of "erring" instead of "falsely recollecting" where the character of the objective reality is emphasized in the psychic material to be reproduced—that is, where something other than a fact of my own psychic life is to be remembered or rather something that may be confirmed or refuted through the memory of others. The reverse of the error in memory in this sense is formed by ignorance. The mechanism of the occurrence of the error invariably indicates that the mental activity concerned had to struggle with some disturbing influence, although the nature of the error need not be determined by the quality of the disturbing idea, which may have remained obscure. It is not out of place to add that the same state of affairs may be assumed in many simple cases of lapses in speaking and writing.

511 East Eleventh Street.

The Return to Barbarism.—The war has left an aftermath characterized as a return to barbarism through regression and inversion of social values. A laboring man earns more than a physician, a chauffeur than a professor in the Sorbonne, while the mopmen are the best paid of any of the university personnel. It is an era of bad taste, egoism, and brutality, and materialism overrides intelligence—a logical demonstration of the outcome of Marxism had the latter ever been successfully introduced. The arm is now more powerful than the brain, for with complete equality conceded one of the two must go under.—*Journal des praticiens.*

Medicolegal Notes.

Practising Medicine — Chiropractor. — The Supreme Court of Illinois holds that Laws 1899, page 273, as amended by Laws 1917, page 579, making it an offense to practise medicine or surgery or treat human ailments without a certificate from the State board of health, was enacted in the exercise of the police power, for the protection of the lives and health of the people, and it is valid unless infringing on constitutional rights. A chiropractor, whose practice consists of adjusting the vertebræ of the spinal column, professes, that court says, a method of treating physical ailments, injuries or deformities that is not within the common meaning of the term "practising medicine," but the General Assembly had a right to define the practice of medicine for the purposes of the act so as to include that method.

Within constitutional limits the General Assembly is the sole judge of what laws shall be enacted for the protection of the public health, and so long as it does not infringe upon inherent or constitutional rights, its determination of what measures and regulations shall be adopted is held by the courts to be conclusive. The Legislature cannot, however, arbitrarily interfere with the enjoyment of rights guaranteed by the Constitution, and cannot invest any board or commission with arbitrary discretion which may be exercised in the interest of a favored few, or which affords opportunity for unjust discrimination. The act provided for examinations of persons applying for licenses to practise medicine and as to those desiring to practise medicine and surgery in all branches, prescribed general rules for an examination. As to those who desired to practise any other system or science of treating human ailments, who did not use medicines internally or externally, or practise operative surgery, it required that examinations should be of a character sufficiently strict to test their qualifications as practitioners. That provision, standing alone, conferred upon the State board of health arbitrary power to grant or refuse licenses in its own discretion and upon its own judgment as to what examination would be sufficient to test the qualification of each applicant for a license. It furnished no standard and no guide and no security to an applicant by which the courts could determine whether the requirements of the board were reasonable or not. The act, however, provided that all examinations should be conducted under rules and regulations prescribed by the board, which should provide for a fair and wholly impartial method of examination. Such rules and regulations, if made would be subject to review by the courts to determine whether reasonable or not. It was held that the statute did not violate any constitutional right.

The action was in debt to recover damages, the statute authorizing a recovery of $100 for the first offense and $200 for each subsequent offense. On the third trial there was a verdict for the plaintiff and assessing damages at $500. The Illinois Supreme Court holds that as the offense did not consist in treating some individual, but in practising medicine generally by treating the public, a first offense meant a first conviction, and as there could not be a judgment for five first offenses, the judgment must be reversed for that reason.—People v. Kane (Ill.), 123 N. E. 265.

Liability for Substitute.—In an action against a physician for breach of contract to attend the plaintiff's wife in childbirth and for the alleged malpractice of a substitute sent by the defendant with the plaintiff's consent, the material facts proven were that the defendant had an agreement to treat the plaintiff's wife, that he found that, owing to pressing professional engagements he would not be able to do so, that it was the custom among physicians in the district in such circumstances to arrange with another physician to take the case, that the defendant did so, that the defendant made no objection to the substitute at the time, but paid him his fee. The trial court charged the jury that the law required the exercise of ordinary care by the defendant in his personal attention on the patient, and also required the exercise of ordinary care by him in the selection of another physician for her. The trial court refused requests to charge that any negligence or lack of skill on the part of the substitute, resulting in injury to the patient, was chargeable to the defendant, regardless of the care exercised by the defendant in his selection of a substitute. The controlling question before the Texas Supreme Court was whether the action of the trial court was correct in giving and refusing these charges.

It was held that the defendant's duty was to exercise ordinary care in the selection of the physician to be sent, as the jury was instructed by the trial court. The defendant could not be held liable for the substitute's negligence or lack of skill, in the absence of facts to establish that the latter was acting as the defendant's agent when he was treating the patient. From the very nature of the employment, the physician who takes the place of another must, while he alone is treating the patient, exercise his own judgment and his own skill; and he is truly an independent contractor. The law applicable to the liability of one medical practitioner for the acts of another who undertakes to look after the former's patients, and the reason therefor, is well condensed in De Forrest v. Wright, 2 Mich. 369, 370, as follows: "To hold that every person, under all circumstances, would be responsible for injuries committed by another person while employed in his behalf involves an absurdity no one would countenance. It would create a penalty from which few could escape; for every man is or ought to be directly or indirectly, nearly or remotely, engaged in the service or on behalf of his fellow man. But from an examination and comparison of the adjudged cases, the rule now seems very clearly to be this: That where the person employed is in the exercise of an independent and distinct employment, and not under the immediate control, direction, or supervision of the employer, the latter is not responsible for the negligence or misdoings of the former." That case was followed by the New Jersey Court of Errors and Appeals in Myers v. Holborn, 58 N. J. Law 193, 33 Atl. 389, or facts very similar to the present case, the court saying: "Dr. P. (the substitute) and the defendant were each of them practicing physicians of this state, having no business connection with one another, except that Dr. P. was attending the patients of the latter while he was temporarily absent. Even if it be admitted, therefore, that Dr. P. was employed by the defendant to attend upon the wife of the plaintiff, that fact did not render the defendant liable for his negligence or want of skill in the performance of this service." It was also held that where it was the long-established custom among physicians in the vicinity for one to send another to those patients the former was unable to attend, the defendant's statement to the physician selected by him that it would be a partnership case could not be construed otherwise than as meaning that the defendant expected to resume charge when his other engagements would permit, and that each for his services would be entitled to compensation. The judgment of the trial court for the defendant was therefore affirmed.—Moore v. Lee (Tex.), 211 S. W. 214.

Expert Evidence—Electric Voltage Sufficient to Cause Death.—In an action for the death of a railroad repairman from a shock from an electric light he was carrying, three regularly practicing physicians who had had some experience in the use of electricity, qualified as experts and testified from their general knowledge, obtained from observation and research in their profession, that the voltage, 115. was sufficient to produce death. One gave the opinion that 65 volts was sufficient to cause death under favorable circumstances, such as existed in the case (the deceased was standing on a wet floor at the time of the accident). Another testified that in his opinion from 50 volts up might produce death under these conditions, and the third testified that 110 volts might be dangerous to life under the most favorable conditions, depending upon the length of time connected. One of the plaintiff's witnesses testified that by coming in contact with a similar domestic wire used in an automobile shop he received a shock that knocked him 10 or 12 feet and rendered him unconscious. The defendant did not introduce any medical experts, but relied solely on the testimony of its electrical experts, who testified that 115 voltage was not sufficient to produce death. It was held to be abundantly proved by the expert witnesses that the voltage received by the deceased was sufficient, under the circumstances, to cause death.—Clinton & O. W. K. Co. v. Dunlap, Oklahoma Supreme Court, 181 Pac. 312.

MEDICAL RECORD.

New York, January 17, 1920.

LIFE EXPECTANCY AFTER OPERATIONS FOR GASTRIC AND DUODENAL ULCER.

A PAPER on this subject, read before the American Surgical Association last June by Donald C. Balfour (*Annals of Surgery*, November, 1919), reports the results of investigations by the Actuarial Society of America, under the direction of Mr. Arthur Hunter, Chief Actuary of the New York Life Insurance Company, of all cases of gastric and duodenal ulcer operated upon at the Mayo Clinic between 1906 and 1915. As Balfour says, unfortunately there is no basis on which the results of the investigation can be compared with the results in nonoperated cases, for not only are no statistics available as to life expectancy in nonoperated cases of gastric and duodenal ulcer, but accurate statistics in this group will probably never be entirely possible, because the uncertainties of diagnosis discount more or less the dependability of such figures. On the other hand, surgical statistics are based on proved lesions, and on lesions in which the medical treatment has failed.

In these observations the results in the gastric and duodenal ulcer groups were compared, then each group's mortality was compared with that of a similar number of the general population corresponding in age and sex. Of 2431 patients operated upon for gastric and duodenal ulcer between 1906 and 1915, all but 108 were traced—certainly a remarkable piece of work in itself. The average age at operation for gastric ulcer was: males, 47; females, 43; for duodenal ulcer, males, 44; females, 42. The operative mortality from all causes in 545 cases of gastric ulcer was 4.5 per cent.; while in 1684 cases of duodenal ulcer it was 2 per cent. Gastric ulcer, therefore, carries twice the operative risk of duodenal ulcer.

Investigation of the mortality in the years following operation shows the following facts: 521 gastric ulcer cases were under observation on an average of 3.6 years, and in that time 88 (17 per cent.) died from all causes; 1,651 duodenal ulcer cases were under observation on an average of 3.4 years, and in that time 85 (approximately 5 per cent.) died from all causes, and 91 cases of both gastric and duodenal ulcer were under observation on an average of 3.8 years, and in that time 9 (10 per cent.) died from all causes. In connection with these figures Mr. Hunter, as quoted by Balfour, says that, while we cannot tell how many lives have been saved by reason of operation for duodenal ulcer, it may safely be stated that the survival of 95 per cent. for three and one-half years after operation is a high tribute to surgery. With such a serious condition as gastric ulcer, a death rate in three and a half years of 17 per cent. of those operated upon seems to be low. While unable to prove the statement, Mr. Hunter believes that a much larger proportion of persons would have died but for operation, and that many years of life in the aggregate were saved through surgical treatment.

The comparative tables showing the number of deaths in the group of 521 persons operated upon for gastric ulcer and 521 persons of the general population with like distribution as to age and sex give the following:

Time following operation.	Deaths in operated.	Deaths in gen. population.
First year	36	8.2
Second year	21	6.5
Third year	11	4.9
Fourth year	7	4.1
Fifth year	7	3.
Sixth year and subsequent..	6	5.6
	88	32.3

A similar comparison of the deaths in 1651 duodenal ulcer cases operated upon shows:

Time following operation.	Deaths in operated.	Deaths in gen. population.
First year	22	24.
Second year	20	18.6
Third year	9	14.3
Fourth year	10	11.2
Fifth year	11	8.3
Sixth year and subsequent..	13	16.7
	85	93.1

In this last series it is rather astonishing to see that the total number of deaths in the first two years after operation is exactly the same as that of the general population group, and that after the second year the mortality is actually less than in the general population group. As Balfour says, these statistics illustrate very strikingly the fact which has always been recognized by surgeons, namely, that gastric ulcer is a much more serious condition than duodenal ulcer, not only from an operative standpoint, but from a standpoint of after-results; and that the patient with a gastric ulcer shows, as a rule, much more evidence of impaired general health than does the patient with duodenal ulcer.

THE SYMPTOMATOLOGY OF EXTRAMEMBRANOUS PREGNANCY.

AN extramembranous pregnancy is when the fetus during gestation escapes through the membranes and comes directly in contact with the

uterine walls. This form of pregnancy offers no one symptom which will affirm the diagnosis before labor takes place, but there is a series of symptoms sufficiently characteristic to lead the practitioner to suspect this abnormal state of affairs, although examination of the after-birth is the only means of making an exact diagnosis.

During a normal gestation, suddenly, with or without cause, a liquid discharge appears, which may or may not be preceded or accompanied by a hemorrhage. The liquid is at times clear, at others more or less tinged with blood. There are no other phenomena than this one symptom, the patient feeling perfectly well and without pain. The discharge appears each day and may be quite profuse. The three principal characters of the discharge are its frequency, its quantity, and usually its rather marked red tinge. It has the stale odor of amniotic fluid.

Palpation may give some useful data. The uterus is less developed than it should be; it is hard, tense, and strongly contracted over the fetus, and if there be a breech presentation—which is the most common in these cases—no ballottement of the cephalic pole can be obtained. In some rare instances bimanual examination affirms the diagnosis of extramembranous gestation if the fingers come into direct contact with a part of the fetus without interposition of the membranes. The little maneuver indicated by Bonnaire, causing the amniotic fluid to flow into the hand during vaginal examination will show the presence of sebaceous matter and other elements characteristic of the amniotic fluid, so that a diagnosis of amniotic hydrorrhea can be made. All these signs may lead one to suspect an extramembranous pregnancy but not more, and a differentiation must yet be made between the discharge of amniotic fluid and decidual hydrorrhea. Examination of the after-birth is, as has been said, the only sure means of making a positive diagnosis. Margination of the placenta has been noted in every case and, although constant, is not enough for making the diagnosis. When the membranes are examined they will be found to form a little pocket at the base of the cord and one is struck by the difference existing between the size of the fetus and the capacity of the amniotic sac and between the diameter of the fetal head and that of the opening in the membranous pocket. It is to be noted that this pocket cannot be mistaken for incomplete membranes because it is often almost closed, having a small regular opening with thickened edges around which it is impossible to separate the amnion from the chorion. There is a complete adhesion between the two membranes and microscopic examination proves that this adhesion is due to cicatricial tissues, thus demonstrating that the rent in the membranes dates back long before labor.

The prognosis is favorable for the mother. The almost constant discharge combined with antiseptic treatment will prevent an ascending infection from taking place in the opened cavity. But on account of the absence of the amniotic fluid and membranes forming the bag of waters, labor may be long and difficult. For the child, on the contrary, the prognosis is very serious; in the majority of cases the fetus is not viable because labor occurs long before term. If the child is born alive it soon dies because during its sojourn outside the membranes it will have been submitted to direct pressure from the uterus, while the absence of amniotic fluid subjects it to the usual malformations provoked by oligoamnios.

The conduct to follow is evident. The patient should be kept in bed, palpation and vaginal examination should be abstained from, and opiate enemata should be given. Should a living child be born, it should receive the usual care given to premature offspring.

DISPENSARY PRACTICE.

EXCEPTING the time of choosing his profession there is no more critical period in the career of a young doctor than that immediately following his internship. A long period of more or less strenuous work has culminated in the "houseship." As house physician or house surgeon he has had a chance to put his knowledge through its paces. The other interns, the nurses, the patients, have taken their orders from him. Only the attendings have enjoyed superiority, and often not even they, in the opinion of the young czar himself.

"Then comes the break, the check, the fall." His service is over. Another czar reigns in his stead. And now comes the real test of his quality as a medical man. During the months of ward work many an intern allows the idea to grow upon him that all the "interesting cases" are to be found in hospital beds. Many feel profoundly relieved that their student days in crowded dispensaries are over. Treating patients with anasarca, or peritonitis, or cavitation, is to them far more thrilling than dealing in albuminuria, or mild appendicitis, or apical infiltration. Because a patient's condition is more desperate it is likely to be considered more interesting, more worth treating.

Our interns today should (and fortunately not a few of them do) take note of the fact that the ambulatory case deserves as much, if not more interest and attention from the profession than does the patient with one foot in the grave. By their increasing willingness to consult a practitioner before their sickness has reached an advanced stage, the laity are showing how the "ounce of prevention" idea is influencing them. For the well-to-do this means going to the doctor before they are so sick that they must call the doctor to them. For the poor it means going to the dispensary before they are so sick that they must go to the wards. For the profession it means recognizing disease in its earliest phases, before the appearance of the less easily mistakable signs of the later stages. So far as the difficulty of the task is concerned, then,

the profession would do well to equip the dispensaries with some of the very best physicians, surgeons, and specialists. This is exactly what is happening in the more forward-looking dispensaries today, particularly in those connected with the medical schools.

But the majority of outpatient departments are still seldom if ever visited by the more prominent men of the institution. (Another reason for lack of enthusiasm on the part of the rising medical generation.) They are often left to the tender mercies of inexperienced men who have been fed up on the greater desirability of ward work, and who can't get it except as hangers-on at rounds.

Certainly a full dispensary and an empty office are the usual lot of the recent hospital graduate. On the empty office we have no comment to make. But the dispensary practice should be developed, studied, regarded as an opportunity for which to be grateful. It deserves greater interest from the younger men, greater recognition from the older. As an agency in prophylactic medicine, in teaching, and in research, the dispensary should rank fully as high as the ward.

Nature of the Grippe Virus.

The materies morbi must be a living contagium; it must be so subtle and of such low molecular weight as to be like a volatile gas; it is by reason of this gas-like property that it can spread rapidly from man to man and also penetrate the respiratory mucosa. In other words this animated vapor is capable of instantaneous contamination of the animal organism. It is because of this property that the expired air again gives exit to it and diffuses the disease. These are the views of Roussy (as expressed in a volume recently issued by Masson of Paris), who held them in 1914 before the appearance of the pestilence. That is, he conceived the existence of such a virus and in time the disease appeared and made good his speculation. The theory is not quite the same as that of the filtrable virus but is not antagonistic to it. Like many other convictions this came about through peculiar personal experience; for the writer, having cared for ordinary influenza patients for many years, believes that he had in his own person contracted the disease not less than one hundred times. This extreme susceptibility or total lack of immunity gave him exceptional opportunities to study the means of transmission. He associated the moment of contagion with a certain peculiar odor about the sick patient and naturally conceived the idea that at this moment of olfactory perception the infectious particles were in the nose and other air passages.

Mental Diseases Cured by Grippe.

The cure of psychoses by intercurrent febrile infectious disease is not a novelty and the same may be said of the temporary arrest of epileptic seizures under the same circumstances. Professor Regis and some of his students in France have placed cases of these types on record and Damaye, who is also a student of Regis, reports others in *Le Bulletin Médical* for December 13, 1919, xlvii, 50. One is as follows: A youth of 20 was interned for a hebephrenic condition which supervened without prodromes after a quarrel with a friend. The excitement set up by the fight did not subside. A sister had died in an insane asylum. The psychosis which developed was extremely complex and not readily summed up in a few sentences. At the close of the first year he was classed as a hebephrenic with orientation slightly defective, incapable of occupying himself or of becoming interested in anything. He was calm through his apathetic state, although originally he had shown violence. When in October, 1919, the grippe appeared in the asylum, he developed the gastroenteric form without high fever. The duration of the temperature is not stated, but it did not exceed 38° C. (100.4° F.). Very soon after this episode, it was noted that the mental state was on the mend. He became able to fix his attention and oriented accurately. The deliriant ideas originally present had quite disappeared. His memory now returned intact and he recalled the entire course of his alienation. In November he was pronounced cured. The author cites another case of the same type in which the curative agency was an attack of angina with temperature of 38.5° C. (101.3° F.). In these cases we cannot give credit to high temperatures, indeed the occurrence is not explicable.

Scorbutus at Lille in 1917.

During an interval of six weeks Baltus saw a total of 17 cases of scurvy in the city of Lille (*Journal des Sciences médicales de Lille*, November 30, 1919, xxxvii, 40). Of this number 7 occurred in children whose ages ran from 7 to 14 years. The remaining patients were all past the age of 50 and one was 87. Every adult had petechiæ, ecchymoses, and hard edema of the feet and legs, and alterations of the gums in varying degree. All had pains in the lower extremities which interfered with locomotion, along with marked weakness and anemia. Not a single child had hemorrhage or edema, but the gum alterations were in evidence, although only to the extent of puffiness. In the child the début was most insidious. Aside from the material just quoted Baltus saw in an orphan asylum four little girls who had seemed in perfect health develop sudden inability to walk or even stand. The cause was not associated with any spinal or joint trouble. At that time scurvy was little known and not until the author found some ecchymotic areas on the lower extremity did he think of this malady. He examined the gums, finding puffiness but no hemorrhage. The principal expression of the disease was, therefore, the paralysis, as it might be termed. In theory there should have been a prompt recovery under orange juice, green vegetables, and fresh air. But unfortunately nothing like this happened and recovery was slow and tedious. Was there some inverted connection between paralysis and ecchymoses? The adults had the latter without the former and the only one of the four orphans who retained some power over her lower limbs showed some ecchymoses. The other children seem to have shown neither paralysis nor ecchymoses.

News of the Week.

For the Protection of Medical Ideas and Inventions.—The Section of Historical Medicine of the New York Academy of Medicine will hold a meeting on Wednesday, February 4, at 8:30 P.M., at the Academy of Medicine, the object of which will be to discuss a subject of interest to all members of the medical profession. A committee appointed by the chairman, and composed of Doctors R. T. Morris and A. L. Soresi, will present practical suggestions regarding the creation of a special medical board to establish and protect the priority of ideas relating to medical subjects; this board would correspond to the patent office. Another important point presented for discussion will be the suggestion to have the board patent in its name all new surgical instruments, and pay a royalty to the inventors, as is done in the case of medical authors, who are paid a royalty for their publications. All physicians are cordially invited to be present, and the discussion will be open to all.

Food Drafts for Europe.—It is reported that the American Bankers' Association will issue drafts to Americans who desire to aid sufferers from lack of food in Europe. The drafts, which may be mailed to Europe and cashed for food at warehouses at Warsaw, Prague, Vienna, Danzig, and other points in the famine territory, will probably be of ten dollars denomination. About 24 pounds of flour, 10 pounds of beans, 5 pounds of lard, 8 pounds of bacon, and 6 cans of condensed milk will be obtainable in exchange for one of the proposed drafts. Should a profit accrue from these transactions it will be employed in feeding undernourished children.

Malt Sugar Syrup for Sugar.—According to the Bureau of Chemistry, United States Department of Agriculture, a sugar substitute is promised in malt sugar syrup, now being made on a commercial scale. It is made from the same grains as beer, and may be made from corn, potatoes, or any plant containing starch. The syrup looks very much like maple syrup and has a flavor somewhat like that of honey.

Names of Blind Requested.—The New York Association for the Blind, 111 East 59th Street, New York City, has made an appeal to the public for the names and addresses of men and women recently becoming blind. The teachers of the association minister to blind persons without regard to race, creed or color.

New Drug Import Regulations.—Under a ruling of the War Trade Board, State Department, effective January 10, narcotics, and salvarsan, neosalvarsan, and all substitutes therefor, may be imported from all countries except Soviet Russia, without individual import licenses.

Gum Opium Arrives.—Two steamships arrived at the port of New York recently from Turkey, their combined cargoes amounting to 75,000 pounds of gum opium, the market value of which is more than $556,800.

Red Cross Activities for 1920.—In a statement recently issued by Dr. Livingston Farrand, of the American Red Cross, it is announced that out of a fund of $30,000,000 available for its work for this year, the society has set aside $15,000,000 for European relief, $13,750,000 for use at home, and $1,250,000 for completing its program in Siberia.

Mary Putnam Jacobi Fellowship.—The Women's Medical Association of New York City offers the Mary Putnam Jacobi Fellowship of $800.00, available for post-graduate study. It is open to any woman physician for work in any of the medical sciences. Applications for the year 1920-1921 must be in the hands of the Committee of Award by April 1, 1920. Applications should be forwarded to the Secretary, Rose Cohen, M.D., 151 West 78th Street, New York City.

Fund for Mental Convalescent Home.—A campaign has been inaugurated to raise a fund of $250,000 for the establishment and maintenance of an institution to be known as the Home and Farm Institute for Mental Convalescents, for sufferers from mental ailments in primary stages. It is intended for the care of those who cannot afford treatment in private institutions. A site for the home has been selected in Sullivan County.

Vital Statistics in New York.—The general death rate for New York State, according to a report issued by Dr. Hermann M. Biggs, New York State Commissioner of Health, was increased slightly in November, 1919, over the preceding month, but was still very much below the average for the month of November during the five years before 1918, the decrease being over 17 per cent. The State's birth rate of 20.4 per thousand population for November was much below the average for that month in the five years 1913-1917. The State's infant mortality rate of 66 for November was 19 points below the average for that month.

Defective Children in England.—Of 533,400 children outside of London examined medically, according to the report of the chief medical officer of the Board of Education, 259,000, or 48.5 per cent., were found to be defective.

Shanghai Cholera Epidemic Ended.—According to press dispatches, the Japanese Government has lifted the ban declaring Shanghai to be an infected port in consequence of the cholera epidemic which originated in June, 1919. Shipping and mail service to and from Shanghai has been resumed.

Kentucky Health Board After "Healers."—Chiropractors, natureopaths and various other "healing paths" are having troublous times in Kentucky. The State Board of Health is making war on them, and the Grand Jury, on information furnished by the board, has indicted six of these would-be practitioners on the charge of practising without license.

Still Practising at Ninety-four.—Dr. William M. Parsons, of Manchester, N. H., is said to have celebrated his ninety-fourth birthday recently by visiting his many patients and carrying out his regular office schedule. He is believed to be the oldest practising physician in New England.

Red Cross Building Destroyed by Fire.—The Red Cross building at Camp Upton was destroyed by fire recently, at a loss of $40,000. The camp fire department had difficulty in saving the group of base hospital buildings, in the center of which the Red Cross building stood. There were 200 patients in the hospital at the time.

Antinarcotic Law Upheld.—Judge John C. Pollock in the United States District Court, Kansas City, Kan., recently held the Harrison antinarcotic act to be constitutional. Eight doctors who were convicted under the statute, and who are serving sentences in the Federal penitentiary at Leavenworth, attacked the law in a petition for a writ of habeas corpus.

Influenza on Ship.—Press notices from Buenos Aires announce that a French steamer from Havre and Vigo, bound for Rio Janeiro and Buenos Aires, arrived at the latter port January 7 with five passengers dead, seven dangerously ill, and a large number suffering from influenza. The ship was ordered into quarantine.

Dr. Horace W. Loeb, of St. Louis, dean of the St. Louis University Medical College, and long editor of the *Annals of Otology,* has been made chief of staff of the Jewish Hospital, succeeding Dr. Herman Tuholske, who recently resigned.

Dr. Harold I. Gosline, of Worcester, Mass., formerly major in the medical corps of the army, has been appointed by the Penal and Charitable Commission of Rhode Island as pathologist at the state institutions at Howard. Dr. Gosline is a graduate of Medical School of Harvard University, class of 1914.

Charitable Bequests.—By the will of the late Mary E. Rowland, formerly of Philadelphia, who died recently at Atlantic City, N. J., bequests of $1,000 each are made to the Home of Our Merciful Savior for Crippled Children, Philadelphia, the Children's Seashore Home, Atlantic City, and the Rush Hospital for Consumption and Allied Diseases, Philadelphia.

By the will of the late Fannie Wienmann, of Philadelphia, the sum of $1,000 is bequeathed to the Federation of Jewish Charities.

By the will of the late Sarah McGonigal, of Philadelphia, the sum of $300 is bequeathed to the Presbyterian Hospital.

By the will of the late Thomas Wollenberger, of Philadelphia, the sum of $1,000 is bequeathed to the Mount Sinai Hospital.

By the will of the late Sarah Dodworth, of Philadelphia, the sum of $3,000 is bequeathed to the Children's Hospital.

Protests Against Vaccination. — The rigid enforcement of the recent order issued by the United States Public Health Service regarding the vaccination against smallpox of all persons entering the United States from certain districts in Canada where smallpox has appeared bids fair to call forth legal proceedings. A number of citizens of Sarnia, Ontario, declare they have been vaccinated two and three times recently, and threaten to take a test case to the United Staes Supreme Court if attempt should be made to force them to undergo another vaccination.

To Combat Cardiac Diseases.—The Association for the Prevention and Relief of Heart Disease, which has headquarters at 325 East Fifty-seventh Street, New York City, has issued a pamphlet outlining its purposes and activities. The organization is now engaged in the establishment of dispensaries for workingmen with crippled hearts in the city hospitals, and also seeks the opening of more convalescent homes to patients of milder type, and the founding of institutions for the permanent care of permanent invalids from the same cause. Dr. Lewis A. Conner is President of the association, and Ray Morris the Treasurer. Dr. Alexander Lambert, Dr. Haven Emerson, Dr. John W. Brannan, and Dr. S. Josephine Baker are Governors. Many laymen are members of the organization.

Nationalization of British Physicians in Prospect. — The medical profession in Great Britain, according to recent cable dispatches, is disturbed over the possibility of the nationalization of the medical service, including hospitals and all institutions in any way connected with the maintenance of the health of the people. Under such a system physicians would become servants of the State like the army and navy officers and civil government employees.

Child Labor Increasing.—According to a statement issued January 3 by the Department of Labor, an appreciable increase has been noted in a number of States in the violations of State laws following the decision of the Supreme Court declaring the Federal child labor law unconstitutional. In one case, according to the statement, 47 out of 53 factories inspected were employing children under 12. In another State, where the minimum age for employment in canneries was 14 years, 721 children under that age, including 50 children not yet 10 years old, were found at work in the summer of 1918.

Obituary Notes.—Dr. MARY CHRISTIANCY, for twenty-two years assistant physician to the Pennsylvania State Hospital for the Insane at Norristown, died on November 18 at the age of 69 years. She was graduated from the Woman's Medical College of Pennsylvania in the class of 1883.

Dr. XAVIER OSWALD WERDER died at Pittsburgh, Pa., on November 21 at the age of 62 years. He was graduated from the New York University Medical College in the class of 1879. He was Professor of Gynecology in the University of Pittsburgh, a member of the Allegheny County Medical Society and of the Medical Society of the State of Pennsylvania, a Fellow of the American Medical Association and of the American College of Surgeons, a member of the American Association of Obstetricians and Gynecologists and of the Southern Surgical and Gynecological Association.

Dr. DAVID H. WARNER died at Prescott, Lebanon County, Pa., on November 24, at the age of 57 years. He was graduated from New York University Medical College in the class of 1886.

Dr. JOHN LOUIS METZGER, Jr., died of heart disease at Philadelphia on December 9 at the age of 29 years. He was graduated from Hahnemann Medical College and Hospital in the class of 1912.

Dr. CHRISTOPHER A. FRAME died of heart disease at Philadelphia on December 12 at the age of 74 years. He was graduated from Pennsylvania Medical University in the class of 1876.

Dr. CLARENCE W. SCHAEFFER died of heart disease at Philadelphia on December 19 at the age of 34 years. He was graduated from the Medico-Chirurgical College in the class of 1907. He was a member of the Philadelphia Pediatric Society and Diagnostician to the Board of Health.

Dr. DANIEL MURRAY CHESTON, formerly of Phila-

delphia, but recently living at Hardwood, Md., died on December 22 at the Chestnut Hill Hospital as a result of injuries received accidentally. He was graduated from the medical department of the University of Pennsylvania in the class of 1864.

Dr. EDWIN A. DOWN, of Hartford, Conn., died December 22, of heart disease, at the age of 63. After his graduation from the College of Physicians and Surgeons, New York, in 1887, he was physician to the Connecticut Hospital for the Insane at Middletown, for four years. He then served as physician to the Hartford Retreat for six years, following which he devoted his time, until his death, to the practice of neuropsychiatry. He was president of the State Board of Charities, and was a member of various medical societies.

Dr. THOMAS J. B. RHOADS died at Boyertown, Pa., on December 24 as a result of heart disease at the age of 82 years. He was graduated from Jefferson Medical College in the class of 1861. He served as surgeon in the United States Army during the Civil War. He was a member of the Berks County Medical Society and the Medical Society of the State of Pennsylvania, and a Fellow of the American Medical Association.

Dr. ELLA RIDGWAY ZIEGLER died at Philadelphia on December 30 at the age of 74 years. She was graduated from the Woman's Medical College in the class of 1874.

Dr. EDGAR H. BYERS died at Philadelphia on January 7 at the age of 53 years. He was graduated from the Jefferson Medical College in the class of 1889.

Dr. HILARY M. CHRISTIAN died at the Presbyterian Hospital, Philadelphia, on January 7 at the age of 61 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1882. He was a member of the Philadelphia County Medical Society, the Philadelphia Gastro-Urinary Society, the American Association of Genito-Urinary Surgeons, the American Urological Association, the Medical Society of the State of Pennsylvania and a Fellow of the American Medical Association. He was Clinical Professor of Genito-Urinary Diseases in the Medico-Chirurgical College.

Dr. THOMAS W. CLARKE died at Philadelphia on January 8 at the age of 46 years. He was graduated from Hahnemann Hospital Medical College in the class of 1896.

Dr. CHARLES MCINTIRE died at Easton, Pa., on January 4 at the age of 73 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1873. He was a member of the Northampton County Medical Society, and of the Medical Society of the State of Pennsylvania, and a Fellow of the American Medical Association and of the American Academy of Medicine. He was for many years Secretary of the American Academy of Medicine and also editor of its *Bulletin* and at one time its President.

Dr. JOHN W. BARNES, of Columbus, Ohio, died of diphtheria, December 29, at the age of 59. He was graduated from the Cincinnati College of Medicine and Surgery in 1889.

Dr. ARTHUR J. LANCE, of Portsmouth, N. H., died suddenly January 3, in his fiftieth year. He was graduated from the University of Vermont College of Medicine in 1893. He specialized in ophthalmology and otolaryngology.

Dr. JOHN LOOMIS, of Jeffersonville, Ind., died December 22 at the age of 99. He was born in Russell, Mass., but had lived in Indiana many years.

Obituary.

WILLIAM SAMUEL GOTTHEIL, M.D.,

NEW YORK.

Dr. WILLIAM S. GOTTHEIL, of this city, died suddenly of heart disease January 8, in his sixty-first year. He was born in Berlin, the son of the Rev. Gustav Gottheil, who for many years was rabbi of Temple Emanu-El, in New York.

Dr. Gottheil was graduated from the College of Physicians and Surgeons in 1881, subsequently specializing in dermatology and syphilology. He was at one time professor of dermatology in the New York School of Clinical Medicine, and in Fordham University Medical School. He was an active member of the New York County Medical Society and the Manhattan Dermatological Society, and was a Fellow of the New York Academy of Medicine. He was the author of a "Manual of General Histology," in 1894; "Illustrated Skin Diseases," 1897, and a work on "Syphilis," 1899, and was a contributor of numerous articles to special and general medical journals.

CHRISTIAN R. HOLMES, M.D.

CINCINNATI, OHIO.

Dr. CHRISTIAN R. HOLMES of Cincinnati, Ohio, died at the New York Post-Graduate Hospital, Jan. 10, after an illness of several months. Dr. Holmes was born at Veile, Denmark, in 1857, receiving his education in Denmark, Germany, and the United States. He was graduated from Miami Medical College, Cincinnati, in 1886, and practised continuously in that city until his retirement, a few months before his death, specializing in ophthalmology, and otolaryngology. From 1888 to 1809 he was ophthalmologist and otologist to the Cincinnati Hospital; from 1890 to 1904 he was professor of otology at Miami Medical College; since 1908 he was consulting ophthalmologist to Cincinnati Hospital, and since 1904, professor of otology at the University of Cincinnati.

Dr. Holmes was an active member of the American Academy of Ophthalmology and Otolaryngology, the American Otological Society, the American Laryngological Association, the American Laryngological, Rhinological, and Otological Society, and the American Medical Association.

For many years Dr. Holmes had been keenly interested in the work of developing the hospital facilities of Cincinnati. He was a leader in the movement which culminated in the erection in that city of one of the most complete general hospitals in the country. He was permanent chairman of the New Hospital Commission, and devoted the greater part of his time latterly to the hospital work. He served as an officer in the Medical Reserve Corps during the World War, the splendid organization of the department of head surgery at Camp Sherman being largely the outcome of his efforts.

Correspondence.

THE CAREER OF DR. ALLAN McLANE HAMILTON.

To the Editor of the Medical Record:

Sir:—When a person has lived through a long professional career, the story of his early and perhaps his most interesting and useful work may become forgotten. It seems to me that this is particularly true in the case of Dr. Hamilton, because his early work was along new lines and was characterized by courage and industry in entering untrodden paths.

Dr. Hamilton published a treatise on "Electrotherapeutics" as early as 1873, when he was only 25 years old and he dedicated this to Dr. William A. Hammond. It is a very good work and showed a sound knowledge of electricity and electrotherapeutics, as it was known at that time. It was later translated into Japanese. He published his treatise on Nervous Diseases five years later and this went into a second edition in 1881. During this period, Dr. Hamilton won the prize of the American Medical Association for an essay on "Diseases of the Lateral Columns of the Spinal Cord." And he made at this time the first observation of the fact that lesions of the tempero-sphernoidal lobe cause disturbances of the sense of smell and taste.

He had always an inventive and mechanical turn of mind and he published in his early books a description of a dynamometer which I think is still the best dynamometer ever invented apart from its not being portable. He invented and described also a gas cautery and a new form of double electrode. He was at this period for a time a health officer, and for a time a dramatic critic.

Dr. Hamilton's's early activities remind us that he was the last link to that group of men who gave distinction to American Neurology fifty years ago. The others were Drs. Meredith Clymer, William A. Hammond, Edward C. Seguin, and George M. Beard. Dr. Hammond was the more dominant and aggressive figure; Dr. Seguin was the most accomplished as a clinician; Dr. Beard was the man of the most originality and acuteness of observation. Dr. Hamilton, who was much the youngest of the group, had a wider range of talent and greater versatility. Already in the early '80's he had achieved a position and had a large practice as a neurologist.

While he was most successful in this line of work during the early part of his career, his interests later changed and he took up more specifically the work of the alienist and the medicolegal practitioner. He became fascinated with the work of the expert and enjoyed the spirit of the contests. He was of the temperament that believes wholly and zealously in the cause with which it is associated. This confidence, combined with intelligence, experience, and ingenuity, made him a very successful and helpful man in the many important and even historical cases with which he was associated.

During this time he edited a system of "Legal Medicine" and wrote his book on "Railway and Other Accidents," besides contributing many articles to medical journals and secular reviews.

Dr. Hamilton was very keen in his appreciation and estimate of human character. He was using, perhaps, his own standards. He could recognize slight but real deviations from the normal, and he did not leave out the clothes in estimating the human make-up.

His fondness for European life and the breaks it made in his regular professional work, interfered in later years with his professional practice. He had travelled extensively and had a large acquaintance socially and professionally in England, France, and Italy. There was something of the unrest about him that goes with a temperamental character and he had any visions which he did not realize. He loved the atmosphere of London and started to practice there for a time. He was fascinated with the beauties of Italy and he had a home and residence for a time in Capri.

Then there came upon him, about ten years before his death, a serious illness which necessitated a surgical operation from which he never entirely recovered and this forced him to a life of comparative quiet. He spent these years largely in writing and composed the life of his grandfather, Alexander Hamilton, and also his own biography. This latter work shows in an entertaining and very picturesque way the varieties of his medical, social, literary, and artistic experiences.

Dr. Hamilton was not only a good friend, but a particularly congenial and engaging host. He had amongst his other gifts a knowledge better than most men and women of how to prepare a dinner, having in it the appeal of good food and artistry in its choice and exhibition. He was supernormal with a cuisine, though this was only an incident of his artistic temperament. He was not a gourmet, but just had the knowledge and good taste. He was a good musician and an artist of considerable skill as a draughtsman. He was a collector of discriminating taste many years before that quality existed to any extent in this country. Though not ecclesiastic in his beliefs, he had a special taste for ecclesiastic things—a fact which showed his early expertness. He possessed an unfailing sense of humor, but his wit was inclined to be of the sardonic quality. He could draw and caricature both his enemies and his friends, but there was never any seriousness in his satire. He made at one time lantern-slides caricaturing the members of the Mediochirurgical Society and exhibited them on a screen with legends attached, some of which passed into history!

Dr. Hamilton had the kind of personality which attracted people to him. He was very fond of some people, and he did not like others, so that his life was adorned with many friendships and enlivened by certain enmities, but he had such lovable traits of character and manner, that even his enemies could not really dislike him very seriously. He was kindhearted, hospitable, and generous and helpful to those whom he liked and was inclined to be especially kind and helpful to the younger men.

Dr. Hamilton, nothwithstanding his experience with life, was in a way a diffident man, avoiding public meetings and discussions. This was not due to a sense of inferiority, rather perhaps to a sense of superiority which was not egotistic or offensive, but dependent on a consciousness of keener sensibilities. He rarely went to medical meetings or came in contact with his professional men in for-

mal discussions. He liked to meet his fellow-men socially, or in private organizations, and one of his last and best pieces of work was to organize and assist in founding the New York Psychiatrical Society, of which he was the first president.

Dr. Hamilton lived a life far from monotony. He reached nearly all the high peaks and sullen depths that experience furnished to mortals. He began his career by winning a prize of the American Medical Association and publishing a creditable book. Then he experienced the threat of a disconcerting law-suit.

He had a filled waiting-room for years and then for a period he was a clientless wanderer. He knew and practised his profession on both continents. He had bright hopes at one time of his talented son's career, and in it he rejoiced. He used to show me some of his son's clever and original work as an officer in the Philippines. But the end came tragically. He felt all the joys and tragedies that come in parental and in conjugal life. He enjoyed his vigorous health, but he also bore for years with genial courage the martyrdom of a depressing, and to him almost revolting invalidism. He went with courage to take his chance with a capital operation in surgery, which indeed saved his life but did not mend it.

In reviewing the career of Dr. Hamilton, there come to me not only feelings of deep regret and of a personal loss over his death, but I feel a particular sorrow as I think of the things which so crippled and thwarted him towards the end of his life. Few men were more generously endowed physically or mentally, than he. He did a great deal. He lived a rich and full life and had a successful career, but he had accidents and incidents which prevented him from achieving all the aims which his natural endowments should have secured for him. As I recall his person and character, his varied talents, his qualities of culture, his fastidious refinement, his rich experience, it seems to me we have no such personality or even a potentiality of it left with us.

CHARLES L. DANA.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, Jan. 2, 1920.

War on Rats.—On New Year's Day the Rat and Mice Destruction Act came into force. By the provisions of this bill the owners of property are made responsible for the rats on their premises. The British military authorities have taken the matter up and the Director-General of Army Medical Service has instructed all general officers commanding-in-chief of commands and districts at home to cooperate with the local authorities as far as the military situation demands. The authorities at the ports, knowing the dangers of plague and its effect on their trade, have been very active. The health authorities of Liverpool have been especially energetic. As far as measures for killing rats are concerned, experience has shown that virus is of little use. The food which has given the best result is either mashed potatoes or cereals flavored with oil of aniseed. Carbonate of barium and red squills have proved the most effective poisons.

Industrial Medicine in Great Britain.—Industrial medicine in all its phases is making great progress in Great Britain but, at the same time, is still susceptible of greater advance. The most encouraging feature in this respect is that it is now recognized that unless the workers are in good health, prosperity will be at a standstill—in fact, that the health of the workers and prosperity go hand in hand. It is pointed out in an editorial in the *Lancet*, Dec. 27, 1919, that judging from a discussion regarding the position of the physician and surgeon in the industrial era, which took place at the recent meeting of the Clinical Congress of the American College of Surgeons held in New York, there is a fuller appreciation in America than in Great Britain of the part which the medical profession can, and indeed must, play in the national and international social problems of the day. As said before, if the workmen of a country are not healthy they will not be contented, will be unable to do good work and the country to which they belong will not be prosperous. Therefore, it is manifestly of vital importance to all concerned that workers should be healthy, and it is equally obvious that this very intimately concerns the medical profession. But, in drawing up plans and schemes calculated to improve the health of those who do manual labor and machine work, who in fact live by the work of their hands, the advice of medical men is seldom sought. This omission, which seems to be a serious, almost fatal omission is in part the fault of the medical men themselves, simply because they are not conversant with their subject. The medical student has a crowded curriculum but, up to the present time, preventive medicine has had little place in it. As the editorial in the *Lancet* says, assuredly the industrial importance of injury and illness should be brought home to the student. As certainly as preventive medicine is the medicine of the future, so is industrial medicine one of its most important departments, economically its most important. A medical school of any considerable size should have a chair of industrial medicine and surgery. While this is an ideal which may be some time in coming in this country, it is an ideal which should be striven for and the medical profession of Great Britain can learn much in this direction from that of America.

The Prince of Wales Hospital, Cardiff, which was established during the war for the after care of disabled and maimed soldiers and sailors, is to be continued for the purpose of doing similar work for civilians. There is no doubt that there is scope for institutions of this kind in peace time and particularly in an industrial region as Wales, where it is said there is one maimed person in every 800. It must be borne in mind that industrial surgery is as important as industrial medicine.

Chair of Psychiatry at Edinburgh University.—A chair of psychiatry has been established at Edinburgh University, and the first professor of that science to be appointed is Dr. George M. Robertson, physician in charge of the Edinburgh Royal Asylum.

Honors for a London Physician.—Sir Bertrand Dawson, a well-known London physician, has been made a baron and in future will be known as Lord Dawson. While this event is not quite unprecedented it is very rare. Indeed the only other British physician who has ever been raised to a peerage was Lister and his title was but the seal set upon an international fame. It is true that Sir Walter Foster, who was made Lord Ilkeston, belonged to the medical profession, but he gained his title wholly by political work, so that really Lord Dawson is the first British medical man to win a title by what may be termed the ordinary routine work of a consultant, although he has been prominent in all that pertains to preventive medicine. He is among the leading consulting physicians of London, is Dean of the Faculty of Medicine in the University of London and is physician to the London Hospital in the East End of the metropolis, the largest London hospital. He is physician-in-ordinary to the King and is also chairman of the Medical Consultative Committee instituted under the Ministery of Health, a position of great responsibility, for upon this committee devolves the important task of reconciling the interests of medicine to those of the public.

Education and the Birth Rate.—In a recent number of the *London Times*, it is noticed editorially that the question of the declining birth rate is exercising seriously the minds of thinkers in the United States. Attention is drawn to a paper read a year ago by Professor Ellen Hayes at Baltimore but published quite recently in *Science*, in which the author meets the arraignment of educated women made by Mr. Dublin some two years ago at the meeting of the American Association for the Advancement of Science. This writer stated that in his opinion the fall in the birth rate was largely due to the higher education of women. Professor Hayes rejects this view with scorn and points out that women have won economic freedom and have the right to choose whether they shall bear children and the number they shall have. It is suggested that in place of trying to increase the number of those born, we might try to increase the number of those that live. In every civilized country an immense number of infants die under one year of age, and a large proportion of these deaths are preventable. Moreover, it is argued that the new freedom of women, even if it be a cause of the diminishing birth rate, is but one of many causes. Difficulties of housing, the postponement of the marriage age, the desire to make better provision for children, all tend to limit the production of children. Consequently, it is at one and the same time untrue and ungenerous to assign blame for the decrease of the birth rate only to the education of women. Likewise it is futile. The movement for the social and economic emancipation of women which had gathered force before the war, gained so great momentum owing to the manner in which they shouldered not only their own burdens but those of the men during the war, that it is almost irresistible; and further, men, for the most part, now recognize the justice of their claims to equality. Efforts in the future will be more directed to the conservation of infant and child life than to the production of children. In this connection it is encouraging to know that the matter of child welfare in recent years has received the study and attention which are its due in Great Britain, owing to the teaching, practical and theoretical, of such men as Dr. Erie Pritchard, the science of rearing healthy children has made great strides. The Ministry of Health, too, appreciates the fact that the conservation of child life is one of the most important problems which comes within its province, and in Great Britain, at any rate, the future years will witness great developments in this direction.

Sir William Osler at Oxford.—Sir William Osler will be best known to posterity as a great teacher of medicine. The deceased Canadian physician was as well known in America as in Great Britain, but a brief account of his work at Oxford may be of interest to the readers of the MEDICAL RECORD. His tenure of the Regius Chair of Medicine at the great English University was fruitful and remarkable in many ways. It is pointed out in an elegant tribute to him in the *London Times* of December 30, that when he came to Oxford in 1905 as a stranger he found the Medical School at a very important period of its development, and he at once recognized its possibilities and devoted himself to the solution of its problems. By his enthusiasm and the charm of his personality he brought about more close and intimate relations between the University and graduates in London teaching schools and thus prevented the possibility of a breach which was in some danger of arising. Osler in his efforts to make of Oxford a great medical school, nevertheless carried on the traditions of his predecessors, and his greatest contribution to Oxford medical studies lay in the development of clinical teaching, while the improvement in clinical teaching owed not a little to his friendships with Oxford doctors. However, his teaching was not confined to clinical medicine, for his own wide intellectual interests led him to regard it as essential that a student should care about the history of his subject, and he gathered young students about him in his own house and used his own valuable library of early medical works to awaken their interest. The personality of Sir William Osler was the characteristic which perhaps made the deepest and most lasting impression. He possessed a perfect genius for friendship and the power of retaining a vivid recollection of all who were brought into contact with him. It may be emphasized that he was specially the friend of Colonial and American undergraduates.

Dysenteric Abscess of the Liver Cured by Emetine Without Operation.—About ten cases of this remarkable therapeutic success have now been recorded, which almost places emetine at the head of specific remedies. The latest case to go on record is that of Chauffard and Françon. Diagnosis was made by puncture and radiography and even after the first injection of emetine improvement was noted. About three weeks were required for a complete cure. Of interest was an aberrant Wassermann, not due to syphilis, but to the amebiasis and abscess. This became negative in about a fortnight: Five injections of emetine were required for a cure.—*La Presse Médicale.*

Progress of Medical Science.

1. "Flat Foot" and Other Static Foot Troubles. Frederic Cotton.
2. Frequent Urination. Frederick D. Davis.
3. Report of Progress in Ophthalmology. Edmund W. Clap.

1. "Flat Foot" and Other Static Foot Troubles.—Frederic J. Cotton classifies foot troubles of static origin as follows: 1. "Flat foot: (*a*) habitual (reducible), which takes in most of the cases; (*b*) rigid, or spastic; (*c*) bony. 2. Short heel-cord with or without flat foot. 3. Contracted foot. 4. Anterior arch trouble: (*a*) "Morton's disease"; (*b*) "fallen" anterior arch. 5. Hallux valgus: (*a*) hallux rigidus. Of all these it is Class 1*a* that fills the orthopedic offices and keeps the shoemaker busy devising and advertising the perfect shoe and the ideal arch support. Each class, with its management, is discussed. The writer's summation of the subject is as follows: 1. Most foot troubles are physiological—"static" in origin. 2.. In a large share, bad shoes are responsible. 3. In many bad habits in use of the feet are responsible. 4. In cases of Class 1*a* decent shoes and properly supervised exercises, properly carried out, will bring about a *cure* in a very large percentage—probably a majority—of the cases, certainly in a majority of the younger cases —below 25 years of age. 5. These are the cases to which plates are too often applied. 6. Plates are still too much used. 7. Plates help, but never cure. 8. "Flat foot" cases, as we meet them, call for either physiological cure—palliation by straps, plates, etc., *then* systematic exercise, or else they do ill under the routine and call for more or less permanent support, or (rather rarely) for radical correction by manipulation or by open operation. 9. Anterior-arch troubles are readily relieved, as a rule—very often not curable. 10. Hallux valgus (and hallux rigidus) may be palliated effectively, but can be cured only by surgery.

2. The Palliative Treatment of Urethral Stricture.—Maximilian Stern expresses the opinion that the end results of palliative treatment of urethral stricture, in cases in which that is possible, are in many respects better than those in which external urethrotomy has been performed, and that every effort should be made to treat these cases by palliative means along definite lines with a well-planned technic. He reached this conclusion in consequence of three striking facts: First, that patients who have been previously operated upon (external urethrotomy) and after a period of neglect require further treatment, are catheterized with great difficulty and often must submit to another external urethrotomy; second, that in these cases, even if catheterization is possible, dilatation is extremely difficult and softening even with the aid of heat is impossible; and, third, that more frequent treatment is required to keep the urethra patent in cases treated palliatively. These patients are not able to remain without catheterization for nearly so long. The writer discusses the cases requiring operation; clinical types of stricture at the bulb; palliative and nonoperative treatment; inflammatory stricture with occlusion of urethra; the operating urethroscope; inflammatory stricture with partial retention; anemic stricture; the irrigating dilator; technic, and results obtained. His conclusions are: 1. That external urethrotomy is not the operation of choice for the cure of urethral stricture at the bulb. 2. That in complicated cases requiring immediate operative interference, cystotomy alone is frequently to be preferred, lowering mortality and yielding better end results in so far as the urethra is concerned. 3. That in uncomplicated cases of acute urinary retention, a ureter catheter inserted into the bladder with the operating urethroscope, followed by rest and other palliative measures, offers better possibilities than surgical procedures. 4. That hyperemia and dilatation as described are valuable adjuncts to the absorption of urethral infiltrates.

8. Heat-Resistant Organisms: A Study of Bacteria Encountered in Heat Sterilization of Surgical Ligatures and Sutures.—Fenger, Cram, and Rudnick, in the course of the experimentation to determine the temperature necessary to insure sterility of the product, obtained more than a hundred cultures, both from the raw, unsterilized ligatures and from those heated at various temperatures. These cultures were examined, and from them fourteen typical specimens were selectd which included all the varieties observed. From these fourteen cultures five distinct types of bacteria were isolated: three spore-forming bacilli and two cocci. All were aerobic and facultative anaerobic and grew at both 20 and 37 C., though somewhat more quickly at the latter temperature. From their studies they found that of five distinct types of heat-resisting bacteria described, including both cocci and bacilli, which commonly occur in raw ligatures and sutures, none were found to be pathogenic. Plain and chromicized ligatures and sutures can be sterilized only by heat. Antiseptics and germicides are of no value in the absence of water. The thermal death point for the five types of bacteria lies between 150 and 160 C. under the conditions found in ligatures and in nonaqueous liquids. Absolute sterility is assured by gradually heating the ligatures in oil or some other suitable nonaqueous liquid up to 160 C. and maintaining this temperature for one hour. The great resistance to heat of the two types of cocci described is a very important fact.

3. A Clinical Lecture on Hypochlorhydria and Air Swallowing.—William Russell, after discussing the symptomatology of hypochlorhydria, and reporting four cases, calls attention to "air swallowing," a condition which has important relations to other gastric disorders. Two such cases are detailed. In the first of these air-swallowing cases there was elicited a history of "pain," which was converted into "fullness and tight-

ness," coming on with the taking of food, increasing as food was swallowed, until eating was stopped owing to the feeling of "fullness"—no more could be swallowed. Prompt relief followed the bringing up of "a lot of wind." The history in this case is quite different from the history obtainable in a case of gastric ulcer, which is the only condition with which it might be confused, if the history of the symptoms were not carefully and critically examined. The phenomena presented by this patient are not very rare, and yet they are not widely recognized. The air is swallowed when the food is taken. The amount swallowed varies in individual instances, and consequently the degree of discomfort varies. In this patient the discomfort was great, because the amount swallowed was considerable. It sometimes gives rise to visible distension; it may lead to pronounced neurosis or neurasthenia; it may act reflexly on heart and vessels, leading to functional angina pectoris.

This peculiar air swallowing when food is taken is different from "air gulping" or "air sucking." Air swallowing is confined mainly to the time food is being taken, although, to a much less degree, it may be continued during the period of discomfort. The "air gulper" swallows air at any time, and it may or may not be induced by an initial stomach discomfort. Air swallowing occurs in both sexes, and probably in children pretty frequently. It may be associated with, but apparently may even be caused by, abnormal gastric secretion, abnormal in the sense of the secretion containing too much or too little hydrochloric acid—that is, either hyperchlorhydria or hypochlorhydria. In the writer's experience it is more common in the latter than in the former. The second case illustrates the combination of hypochlorhydria with air swallowing persisting after removal of the appendix. The points of special interest in this case are (1) the air swallowing, which stopped when the hypochlorhydria was successfully treated; (2) that it was not a case of "appendicular dyspepsia," which presumably was the diagnosis which led to the removal of the appendix; and (3) the fall of 20 mm. Hg. when the gastric condition was rectified.

3. The Practical Aspects of Quarantine for Influenza.—T. H. Whitelaw, reviewing the application of quarantine in the Province of Alberta, Canada, and in Chicago, during the 1918 epidemic, concludes that no public health law which has not the endorsement of the public generally can ever be reasonably well enforced. Human nature cannot be altered, but laws can be, and it seems desirable that regulations regarding quarantine should be revised in such a way as to secure the maximum co-operation of the community, including the medical profession, in their enforcement. The apparent success of the method followed in Chicago in connection with the influenza cases suggests that the same method might work out advantageously in many of the minor and less serious infections now placarded under the name of "modified" quarantine, and secure a much more efficient control of these infections by health departments. It would penalize by a placard only those who failed to report and submit to the instructions of health officials, and would thus be a strong incentive in securing the co-operation of the public generally with health departments in the prevention, as far as possible, of the minor infections which are unfortunately regarded so lightly by the majority of the community in spite of the undoubted fact that many untimely deaths result from them.

Revue médicale de la suisse Romande.

November, 1919, xxxix, 11.

Child Influenza at Geneva.—D'Espine attempts to trace the pandemic to the Eastern battle front in the spring of 1916, where it was hushed up by the German military censorship. In the following winter there appeared in northern France among the English troops a purulent bronchitis, accompanied by cyanosis, and followed frequently by death. Somewhat later the same affection appeared at Aldershot—"purulent bronchitis with cyanosis, and a mortality of 50 per cent." This preceded the pandemic by one year. In the pediatric clinic at Geneva early in 1918, and months before the pandemic, cases of asphyxiating bronchopneumonia were seen and the autopsy finds were those of the later pandemic. The bronchopneumonias were not primary, but followed simple colds. On February 3 cases of ordinary cropous pneumonia of fulminating type were recorded at the time as example of pneumococcemia. Two of these croupous cases were accompanied by two others with bronchopneumonia. In these cases influenza was excluded by the absence of Pfeiffer's bacillus. Yet the finds at autopsy agreed throughout with those seen later at the height of the pandemic. The lobar cases were associated with precocious empyema, and the bronchopneumonic cases were hemorrhagic. The last of this group of cases preceded the pandemic by only three weeks. It thus appears that the *genius epidemicus* was local, and that the pandemic, perhaps not essentially malignant, found the soil prepared for its malignant manifestations. It will be recalled that the summer mortality was especially high in Switzerland. The succession of cases ceased in March, 1919, after more than a year's continuous incidence. The Pfeifferian influenza of 1890 did not disappear for about five years.

New Conception of Epilepsy.—Hartenberg evolves the following theory on a basis of clinical and experimental evidence. Many facts go to show that in a seizure there is a sudden arrest of functions of the brain without any reference to convulsions. These inhibitions, as seen in abortive and partial attacks, may be limited to a few functions. Especially in epileptic equivalents is this in evidence. These are seen in the earliest inception of the disease, and often form a background on which occur convulsive seizures. Thus the woman who has a single seizure during the menses may have daily some petty inhibition. In the actual crisis we see inhibitions at the start. Loss of consciousness is one. Loss of muscular tonus which causes the fall is another. The grand crisis is chiefly inhibition. The convulsion is not an inhibition, but a phenomenon of excitability which develops on a basis of inhibition. It stands in some definite association with coma, which the author classes as an inhibitory phenomenon. This association of convulsion and coma is not peculiar to epilepsy, but is universal. Coma is due to sudden anemia of the brain and the latter is necessary for the convulsive state. Experimentally shutting off the cerebral blood supply will elicit convulsions. But it may be claimed plausibly that while convulsions are not an inhibition they are made possible by suppression of a bridling force which the inhibition releases. The convulsions are due to the activity of certain basal motor nuclei, but are only made possible by a cortical motor inhibition. Thus the author takes issue with the theory that convulsions originate in the motor cells of the cortex. Sleep favors inhibition and explains nocturnal attacks. Bromides can abort convulsions, but have no influence on the petty manifestations (inhibitions), and bromides act upon the cortical motor cells. Thus far the author has given us nothing actually new, but now he calls attention to the action of strychnia in epileptics. In theory it should aggravate convulsive phenomena, but actually has the opposite action. Six cases are cited in which it appears that systematic doses of strychnia reduce notably the number of accesses. Even heroic doses of the alkaloid cannot be made to augment the latter. The author does not apparently advocate strychnia as a method of treatment.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK

Stated Meeting, Held December 22, 1919.

THE PRESIDENT, DR. CHARLES H. PECK, IN THE CHAIR.

Address of Retiring President.—Dr. CHARLES H. PECK made a brief address in which he expressed his thanks to the members for their active interest in the meetings of the past year and to the loyal support they had given to make proceedings of the County Society, the representative body of the medical profession of the most powerful city in the world, worthy to be considered the sound and sane judgment of that profession. Much of the important work of the Society was necessarily carried on in its executive sessions—the consideration of important legislation, the shaping of policies of far-reaching import to the profession and public at large, the discipline and control of those who would injure their good name or lower the standards of professional conduct. It was the most important that these executive sessions should truly represent the best sentiments of the whole society and not simply the views of a small party or clique who might happen to control the vote at a poorly attended meeting. A committee had been appointed to consider possible changes in their methods of conducting the executive work of the Society which might help to eliminate some of the faults and weaknesses of the present system. This committee should receive the earnest support and assistance of the members in every possible way, so that any change in the constitution or by-laws might represent the best judgment of the Society as a whole and show real constructive improvement in their methods of procedure. The scientific sessions should not be crowded out or permitted to become of minor importance. The County Society could and did furnish an audience worthy of any scientific presentation and one to stimulate readers of papers to their best efforts, whenever an attractive program was presented. The allotment of time between the executive and scientific sessions should be planned in some way to avoid undue curtailment of the latter, or its actual abandonment at any meeting, as happened at one meeting during the past year. Of the many important matters before the Society during the past year, Compulsory Health Insurance, Narcotic Drug Control, the Registration Bill, future plans for control of violations of the Medical Practice Act were worthy of special mention. He feared the members had not yet understood the significance of the announcement made at the last meeting, that, on account of increased cost and lack of funds, the Society had been forced to abandon its prosecution of illegal practitioners in this city, so long carried on by their able counsel, Mr. Whiteside, and his predecessors. This work had for many years been in the nature of a voluntary contribution by the County Society to the welfare of the public and the medical profession of the city. It must now be turned over to the District Attorney's office. These were only a few of the important matters which would come before the Society during the coming year. Dr. Peck thanked the committees which had devoted so much of their time and energy to the work of the Society during the past year, and especially their chairmen on whose shoulders so much of the burden had fallen, and the counsel of the Society, Mr. Whiteside. In conclusion, Dr. Peck congratulated the Society in having at their command, for help and guidance in solving the many important problems to come before them, the strong hand and sane judgment of their incoming president, Dr. Charles H. Chetwood.

Endocrinology and Gynecological Practice.—Dr. FREDERIC C. HOLDEN read this paper, in which he quoted from a number of investigators in the field of endocrinology to show the confusion prevailing at the present time in reference to this subject. He said he would not attempt to speak of endocrinology as applied to general medicine, but would limit himself to a few rational suggestions for its application in gynecology. Amenorrhea, primary in type, in young girls, when originating in a manner not possible of demonstration by the usual methods of examination, had been treated for many years by tonics, emmenagogues, perhaps by operative interference, or dismissed as the result of a developmental abnormality impossible to rectify in any way. A certain proportion of these cases were of course hopeless from the start, so far as the possibility of instituting menstruation was concerned. Many of these cases might be classified under the caption Froelich's syndrome or adipose-genital dystrophy. In these cases the amenorrhea had been considered to be a result of the obesity; it was but a part of the clinical picture of adiposity and sexual hypoplasia due largely to hypopituitarism. Amenorrhea when suspected of being a part of ductless gland perversion might be benefited by entire pituitary substance combined with corpus luteum or entire ovarian substance and thyroid. In cases of adiposogenital dystrophy, the pituitary needed marked stimulation. Ovarian substance and corpus luteum were required, but the ovary as a stimulator of menstruation had been to his mind overemphasized. Its coadjutors, the thyroid, adrenal, and pituitary were of vast importance. Dysmenorrhea was much less often amenable to ductless gland therapy. It might, however, be induced by a mild degree of genital hypoplasia in which the uterine and genital growth had been retarded somewhere between the infantile and pubescent stages. He had seen this type of case apparently benefited by thyroid and suprarenal substances. Menstrual headaches might be caused by hypopituitarism. Sterility was, of course, produced by many factors beyond the control of the endocrinologist. In treating a given case of sterility it must be borne in mind that over 40 per cent. of the cases of primary sterility, and still a larger percentage of the secondary type, were hopeless from the start, due to anatomical developmental abnormalities, neoplasms, or the ravages of inflammatory disease. There was no doubt that many operations formerly performed for the relief of sterility were done without giving due consideration to the entire body metabolism. This danger applied more to the gynecologist than to the general practitioner in that his vision was limited to the pelvis. Undoubtedly many cases of sterility responded to treatment by ovarian substance, and this combined with thyroid, suprarenal, or pituitary. The ovarian substance and corpus luteum should surely be given and the blood pressure and general metabolism used as an indicator as to whether thyroid or pituitary was indicated as a coadjutor. Active, robust patients exhibiting a high blood pressure seemed best influenced by thyroid association, while the asthenic type of individuals might benefit by association with pituitary substance. Nausea and vomiting of pregnancy responded in most cases to dietetic and psychical regulation. He had, however, recently seen several cases in which, after the usual methods failed, relief seemed to be obtained by the administration of corpus luteum. This might be administered by mouth, but the results seemed better if the preparation were put up in ampules and given hypodermically. He had seen no benefit from the administration of endocrines in threatened abortion, but in the hands of others it was reported to have gained results. In the type of cases many times classified as idiopathic fibrosis uteri, in which the pathologist reported after operation a normal uterus, were secondary to hypothyroid function and would respond to thyroid and posterior pituitary substance. By some endocrinologists the mammary gland and placental extracts were used upon the theory that they were the principal generators of an inhibitory substance upon the function of menstruation. Menopause symptoms, both artificial and natural, had for some time been subjected to ductless gland therapy with excellent results. The psychical rôle was a prominent factor in the production of menopause symptoms, and adverse suggestion should be avoided as much as possible. In cases in which the removal of both ovaries seemed necessary as a result of inflammatotry disease, he felt sure that emphasis upon the fact of removal tended to render less stable the patient's nervous mechanism. He postponed the mention of removal of the ovaries as long as possible and in the interim administered bromides with entire ovarian substance and corpus luteum and he felt sure that the annoying menopause symptoms were thus greatly mitigated, and in many cases they were practically overcome. It was in the menopause cases, both natural and surgical, that in his hands ductless gland sub-

stances had given the best results. Postoperatively they were well accustomed to the use of ductless gland substances as adrenalin and pituitary substance. Thus, almost without being aware of the fact, they had all added endocrines to their therapeutic armamentarium. The question was whether they could advance in this field or whether they were likely to become faddists. Kaurosis vulvæ and senile pruritus were conditions in which it had been noted for some time that ovarian substance and corpus luteum were of benefit. The dosage was of necessity indefinite because the amount of hormone varied in the same gland in different animals and at different times of the year and after methods of preparation. A general statement that he felt was applicable to endocrine therapy was that the doses had been too large. Two and one-half grains of corpus luteum a day would, as a rule, accomplish as much as 5 grains three times a day. One-half a grain of pituitary, three times a day, was as a rule sufficient. The desirability of small doses of thyroid need but be mentioned. Large doses of gland substances produced toxicity in many instances. While endocrinology must occupy a definite position in gynecology this position was a very minor rôle. He feared overenthusiasm and the application of endocrine therapy in cases in which the clinical picture was produced by local pathologycal conditions.

Endocrine Treatment in the Sterility of Women.—Dr. ARNOLD STURMDORF presented this communication, in which he said that to arrive at any true estimation of endocrine treatment in the cure of sterility it was essential to govern our considerations by established therapeutic postulates which, reduced to their simplest form, demanded the logical "Why, When, and How" of the method. One must know why endocrines were indicated in order to determine *when* they were indicated, and to formulate the *how* of their administration. From the therapeutic viewpoint the term sterility was purely relative. Ovulation, fertilization, and nidation, constituted the cardinal phases in the chronological cycle of conception, and any perversion in their normal occurrence determined sterility. We could not create a function, we could only attempt to activate one existing in a latent state, stimulate one that was deficient, or possibly mobilize one that was tentatively inhibited. The subtile biotactic factors that dominated ovular fertilization and nidation, were all susceptible to inhibiting influences, temporary or permanent, local or systemic, most of which involved problems far beyond our diagnostic horizon and therapeutic scope. The study of endocrinopathic sterility must begin and end with the development and function of the ovary as a link which was reciprocally dominated by every other link in the endocrine chain. The domination of the endocrines on the functional activity of the ovaries manifested itself from fetal life throughout the reproductive period to the stage of senescence. On the other hand, just as the determination of sex was decided in the ovum before fertilization, so the future fertility or sterility of the individual was frequently an ovular preordination governed by teratological laws and not those of endocrinology. We know that endocrinological disturbances could and did involve the reproductive organs, but we did *not* know how or why such involvement occurred. After calling attention to certain of the relations of the various glands to the female genitalia the speaker stated that every phase in the clinical problem of endocrinology revolved around the question of diagnosis. Such a diagnosis obviously implied in a given case, the *exclusion of every other pathogenic factor* in the causation of sterility and the elicitation of evident pathognomonic endocrine stigmata. Here we encountered our limitations for, in the present state of our knowledge, it was always difficult and frequently impossible to fulfill these demands. The nearer the symptom-complex conformed to a fully developed or readily demonstrable endocrinological type, the farther the sterility receded from therapeutic consideration. No one would attempt to treat the sterility of acromegaly, Graves' disease, myxodema, or Addson's disease. It was the woman with the ill-defined, obscure, and dubiously suggestive stigmata of endocrine disturbance, whose sterility offered the most fertile field for endocrine exploitation. The elicitation of semiologic criteria in these cases demanded the minutest analytical scrutiny of anamnestic, objective, and subjective details. To quote from Timme: "Never be satisfied with the apparently simple answer that might superficially appear, but always insist of tracing back to first beginnings even the most minute complaints referable to endocrine disturbance." The patient was then to be treated—irrespective of her actual gynecological complaints—on the basis of the original internal gland at fault. The application of direct functional tests, such as complement fixations and deviations, specific ferment reactions, adrenal mydriasis test, the hypophysis test, metabolic studies and sugar tolerance tests along the lines of Abderhalden's theories on the biochemical reactions among the protective or defensive body ferments, while as yet in their probationary stage, gave promise of future light in this perplexing semiologic labyrinth. The diagnostic and therapeutic problems became even more complicated in cases which revealed evidences of an endocrinopathic disturbance plus insidious gynecological infection. Often a vicious circle was established, in which the sterility with its ovarian origin presented the cause and not the result of a general endocrine disorder. If the same minute analytical scrutiny as applied to sterile women were applied to fertile women, it would reveal some evidence of endocrine disturbance in every instance, for paradoxical as it might appear, we found fecundity in pronounced endocrinipathics as we found sterility on normal women. To treat every case of sterility with endocrines, as recently advocated, was about as rational as to curette or incise every cervix for the same purpose, and would probably yield about the same results. It must always be borne in mind that we could not treat the sterility as such, we could only counteract some apparent underlying factor. Endocrinopathic sterility was neither a hypo, hyper, nor dysfunction of the ovary; the ovules were there, but ovulation was in abeyance; whether this was due to the absence of an activating or the presence of an inhibiting hormone we did not know, we could not tell, and could not consequently formulate any specific therapeutic indications. The speaker pointed out a number of the fallacies in connection with the theories upon which corpus luteum treatment for sterility were based, among them the fact that the active principles of corpus luteum were cyclic, that each phase must necessarily develop a corresponding gradation in biochemic potency; the degree of such potency could not possibly be the same throughout its monthly cycle, for if it were there could be neither beginning nor end to menstruation. This obvious postulate was entirely ignored in the preparation and administration of the available corpus luteum products and explained, in part at least, the contradictory results of their therapeutic application. Therapeutically both adrenalin and pituitrin exercised purely temporary effects on the genitalia; they did not replace the functional activity of the gland from which they were derived. When they knew "Why, When, and How," each of the internal secretions stimulated, or inhibited, when they had learned to recognize synergists and antagonists; when they could formulate their normal and pathological biochemical equations; when the pharmacological potentialities of animal extracts as applied to human functions were established, then, and not until then, would the "Why, When and How," of endocrine treatment in sterility emerge from pure empiricism into a rational practice based upon fixed fundamental principles.

Dr. WILLIAM W. HERRICK said if we were good or bad, wise or foolish, tall or short, fat or thin, successful or unsuccessful according to the balance of the varied functions of our endocrines, there was in the thought a comforting release from accountability. That the fault might be in our glands and not in ourselves that many of us were underlings might give a measure of satisfaction. However, just as we were unable to dispense widely with courts because the larger proportion of the inmates of our jails were sick men in one sense or another, so those of us interested in internal medicine might not willingly abandon to the endocrinologist the entire range of medicine. To the internist the glands of internal secretion seemed at present the chief field of medical speculation with the majority interest on the long side of the market. A note of conservation would seem in order and an investigation of underlying values wise. We were ready to admit the facts con-

cerning hyperthyroidism. Long series of clinical observations, supplemented by the findings of the laboratory, capped by calorimetry and the careful work of Dr. Kendall in the isolation of thyroin seemed to have brought our knowledge to a very satisfactory state, so that therapy was based upon apparent facts and was correspondingly successful. In the obverse condition, that of thyroid intoxication or overactivity, we were less secure. To be sure, the clinical picture was generally clear. The calorimeter enabled us to estimate with some accuracy the degree of the disturbance. Rest, certain drugs, irradiation, and surgery supplied means of treatment that were exceedingly helpful. However, when we attempted to fathom the relations of thyroid intoxication to the sympathetic nervous system, the cardiovascular system, and the other endocrines we encountered at once a complex too vast to compass with our present knowledge. In considering the pituitary gland we were taking a still further step into the unknown. To be sure, the anatomical divisions of this organ and their function were roughly known and the grosser pathological changes were recognizable clinically. An active principle, pituitrin, was of limited but real therapeutic value. The substitution therapy of diseases of the hypophysis was far from satisfactory, although a certain measure of success has been achieved in the various phases of the so-called Froehlich's syndrome. We knew even less of the adrenals than of the hypophysis. Again a valuable hormone has been isolated. We were aware of the clinical manifestations of grave changes in structure or function of this gland. The complex relationship to the vegetative nervous system, the cardiovascular system and the other endocrines was again a baffling complex, while the substitution therapy was again disappointing. Consideration of the gonads has been amply taken up by other speakers. Regarding the thymus one might accept any opinion he might choose. There was a sufficient variety to suit all sorts of opinion. The contradictory reports of experimental workers and of clinicians give ample proof of our lack of definite knowledge of this gland. For the present the internist might perhaps content himself with recognition of the more marked changes in structure which gave rise to mechanical symptoms and the status thymolymphaticus. A few days ago a group of senior students presented a young man suffering from asthenia, low blood pressure and a subnormal temperature, and who showed a few flecks of subcutaneous pigment. Having acquired what one might call the endocrine bias, these students had adopted a preconceived idea that such a case was necessarily one of hypoadrenalism. Rather an elaborate study of the blood sugar values and the response to adrenalin injection had been made which seemed to bear out the premises. The only flaw in the argument was that an ordinary physical examination revealed an early tuberculosis of the right upper lobe. No one could deny that the patient might have deficient adrenals, but he dared predict that rest, fresh air, and ample food would accomplish much more in this case than treatment with adrenal extract. This case might serve to emphasize what would seem of fundamental importance, namely, that back of the endocrines and responsible for their disturbance other conditions might lie. These might be infections, metabolic disorders, psychic states which might be entirely overlooked if one's vision was limited. Was it not well to emphasize certain facts with which pathologists were familiar, that the thymus gland diminished in size, or even largely disappeared as a result of prolonged, wasting disease; that posterior basilar meningitis produced disturbance of the pituitary gland, which might be expressed as a diabetes insipidus, that, as Mills had shown, the tastes were profoundly affected in pneumococcic infections. The effect of infection, focal and otherwise, on the thyroid gland has been emphasized by various observers. The acute degeneration of the adrenals found in those dying from diphtheria was well known. Those of us who had lately seen hundreds of necropsies in soldiers dying from acute disease were much impressed with the acute degeneration of the adrenals in these cases. The diminution of chromaffin substance, the cloudy swelling, the fatty changes, the not infrequent hemorrhages were notable. The disturbances of the menopause might not always be due to ovarian hypofunction; a possible early renal insufficiency or cardiac disturbance, or the pronounced anaemia which often accompanied the menorrhagias of this period, were examples of considerations not to be left out of account. Dr. Herrick emphasized the association of the endocrines with the entire complex of the body frame and the futility of considering these glands as structures apart from the whole. The specialist in endocrinology was to be encouraged. We needed his pioneer enthusiasm. It was for him to draw the clinical picture, not of the grosser changes which all of us could recognize, but of the *formes frustes*, the less pronounced variations from the normal. These pictures ought not to be sketched by fancy or imagination, or spring from bare empiricism, but would be prized, as they were based not only on clinical observation and impression, but on a correlation of this with laboratory study and necropsy findings.

Dr. WALTER TIMME said the discussion of this subject this evening had recalled that some six or seven years ago a paper was read on the "Sins of Commission and Omission in Gynecology" and Dr. Cragin in discussing it said there were only sins of commission, there were no sins of omission. This evening's proceedings made that point worth remembering. In gynecology only a portion of endocrinology was applicable and in their field the gynecologists would perhaps agree among themselves. As a matter of fact, they had shown no vital disagreement. Dr. Bandler stated that he had success in endocrine therapy and Dr. Sturmdorf that the problem of endocrinological sterility revolved around diagnosis and that diagnosis implied the exclusion of every other pathogenic factor before the endocrinological was tenable, and both were right. Perhaps it needed a neurologist to straighten out the affairs of the family. Dr. Holden discussed endocrine therapy in gynecological practice, but his discussion of the subject was much broader than appeared from the title of the paper. One had to consider the whole field of endocrine function before he could limit himself to any particular section. Endocrine therapy should be directed not to such a point as sterility, or headache, or pigmentation; one must go behind such symptoms and study the patient he was treating. If one could by chance hit upon the proper treatment in a given case then the symptoms depending on that disturbance disappeared. That was merely empirical. The proper way to approach the problem was not from one minor point, but from the broader standpoint of the subject as a whole. Dr. Holden stated that we knew very little of the ovarian hormones and that the adrenalin hormone was the only one that had been isolated. That was not quite correct. Dr. Kendall had isolated the thyroid hormone and Dr. Robertson had isolated tethelin from the anterior lobe of the pituitary. We could not as yet present the whole subject of endocrinology from the etiology of a disturbance through to the treatment in a well-ordered and logical manner, but there were very few diseases in which this could be done, and in spite of the gaps in our knowledge we treated many cases successfully and are filling in the gaps year by year. Dr. Holden had said that amenorrhea in the Froehlich type could be helped by a combination of pituitarin and luetin. In boys with Froelich's syndrome very good results could be had with anterior pituitary injections. This emphasized one statement that Dr. Sturmdorf made, namely, that we could only stimulate a function but that we could not produce a gland where no normal gland was present. In many cases of Froehlich's disease boys have been helped by anterior lobe of the pituitary, given by feeding and hypodermically. Dr. Timme objected to the designation of endocrine disturbances by terms suggesting an entity such as Froehlich's disease, status lymphaticus, Addison's disease, etc., because with or without our help they passed on to other conditions. These co-called syndromes were only cross sections in dynamic progressive conditions and if looked at in this way a much greater progress in their understanding would be possible than if they were regarded as definite diseases, such as pneumonia or typhoid fever. Dr. Holden mentioned menstrual headaches as produced by hyperpituitarism. The headaches that accompanied pituitary disturbance were not due, as a rule, to glandular activity but to a mechanistic series of events. The pituitary gland became hyperplastic, but its increase

in size in the sella turcica, in a space too small to accommodate it gave rise to headache. After years these headaches might cease as the result of the enlarged gland eroding the sella turcica so that it could function without infringing on the capsule. This relief might be brought about earlier by giving pituitary substance so that the demand on the gland might be lessened and in these cases the feeding of posterior pituitary lobe had been eminently successful. Dr. Holden, in speaking of specific methods of treatment, stated that one and one-half or two grains of corpus luteum were as efficient as five grains three times a day; and he was right on that point; but when he said that one-half a grain of pituitary was sufficient in gynecological disturbances we must disagree for the reason that occasionally one must give much greater doses, and keep them up much longer—perhaps for as long as one must administer thyroid in myxodema—and that was forever. Where the pituitary was enclosed in a small sella turcica the feeding of pituitary must be kept up indefinitely in the smallest possible doses the patient felt were helping him, and the patient himself became very adept in regulating his dose. Dr. Sturmdorf, he thought, had the right idea in realizing the limitations of endocrinology in a special field like gynecology, and in warning against the indiscriminate use of endocrine therapy in gynecology. Dr. Bandler had stated that it was not necessary to understand just how a patient had come to a certain condition. Dr. Timme could not agree on that point. If one said a patient needed thyroid, pituitary, or a combination of glandular extracts, the question was by what process did the patient arrive at his abnormal state; otherwise such treatment would be more or less empirical. He felt that an understanding of the therapy would certainly be helped by knowing the process by which these patients reached their present condition. Dr. Sturmdorf had mentioned the fact that sterility need not be an endocrine defect or anomaly and that it was important that everything else that might cause it be excluded before attempting to apply glandular therapy, even though such therapy might be a powerful adjunct to other treatment. Dr. Herrick had said that from the standpoint of the internist there was but one glandular disturbance, hypothyroidism, about which they possessed definite knowledge. Unfortunately, even of that they were not so sure. Dr. Timme stated that they had yet to understand which were hypothyroid cases and which adrenal, and calorimetric tests had not helped them in that respect. The case of hypoadrenalism that had tuberculosis he did not think fitted into this discussion. because the fact that the man had an apical tuberculosis did not exclude the condition of hypoadrenalism. As a matter of fact, Dr. Pottenger had observed that long before tuberculous lesions could be demonstrated in tuberculosis there was a hypoadrenalism. Whether endocrine therapy was to be applied specifically to sterility, headache, pigmentation, or to lower blood pressure, it should only be applied as it fit into the picture of the patient as a whole. The important point was that one should understand his patient long before he attempted to treat him for one of these particular complaints. One might ask how Addison's disease was treated or how to treat Graves' disease. If one knew just how to treat these diseases it could be told in three lines. As it was, one treated each patient and not his disease, though incidentally the disease might get better. Hence the multiplicity of methods adopted to conform to the individual need.

Dr. STURMDORF, in closing, said the object of his paper was to elicit, if possible, the "rationale" of endocrine treatment in the sterility of women; this object was not realized by the present discussion. He did not question that every woman reported as cured of her sterility by endocrines was possessed of a baby. He did not question facts. but he disputed their interpretation. The most significant feature in all the enthusiastic records of successes was the omission of failures and their explanation; surely no method of treatment known today could boast 100 per cent. cures, not even mercury or salvarsan in syphilis. The demonstration of endocrinopathic stigmata in a given case did not necessarily prove the endocrinopathic cause of the sterility, and a subsequent fecundity in such a case did not prove the cure by endocrines. The annals of medicine were glutted with marvellous cures that did *not* cure, from tuberculosis to cancer and from locomotor ataxia to epilepsy. All readily demonstrable types of endocrine disturbances demanded a lifelong substitution treatment, and at the present time the diagnosis of functional temporary types was at best problematical and the results of their treatment questionable. The doses were gradually being reduced to infinitesimal proportion and might soon disappear entirely.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Stated Meeting, Wednesday, October 1, 1919.

THE PRESIDENT, DR. WILLIAM J. TAYLOR, IN THE CHAIR.

Brachial Birth Palsy, A Pseudo Paralysis of Shoulder-Joint Origin.—Dr. T. TURNER THOMAS in presenting this paper stated that obstetrical or brachial birth palsy represented only one phase of a much larger shoulder joint problem. Almost, if not all shoulder joint injuries were associated with a brachial paralysis, palsy, or weakness of varying degree and duration. Very rarely would an actual nerve rupture be associated with the paralysis. The best evidence of the absence of such a nerve rupture was said to be the almost uniform and gradual disappearance of the paralysis. This was easily proven in connection with the adult cases, and seemed to be true of the obstetrical, in which the paralysis was usually of longer duration and more difficult to follow up. With the crippling of the limb persisting to adult life it would probably be found in all cases that a posterior dislocation of the shoulder was associated, often with some moderate permanent disturbance in the elbow joint. In obstetrical paralysis, soon after birth, there was a profound and almost, if not complete, paralysis of the whole limb, and not a paralysis limited to the small Duchenne-Erb group of muscles. This extensive paralysis, the author said, was best explained by the inclusion of the branches of the brachial plexus in an axillary inflammation consequent upon a birth injury of the shoulder joint. The extravasation into the axilla, of blood and synovial fluid, caused an immediate inflammation, and later, cicatricial tissue, all of which was probably absorbed in time, thus accounting for the disappearance of the paralysis. Such a pathology, Dr. Thomas said, had been well established by operative and post-mortem findings in the obstetrical and adult cases. The Duchenne-Erb localization of the paralysis by electrical reaction to the deltoid, biceps, brachialis anticus (Duchenne and Erb), infraspinatus (Duchenne) and supinators of the forearm (Erb), while widely accepted, was not corroborated. In his first four cases Duchenne had found posterior dislocation of the shoulder which he had said occurred at birth and was chiefly responsible for the paralysis. He had thought, however, that some of the paralysis was due to injury of the brachial plexus. In four later cases he did not find dislocation of the shoulder and attributed the paralysis entirely to injury of the brachial plexus. Since then, Dr. Thomas said, practically nothing had been said of a shoulder joint origin, the dislocations passing unrecognized, and all cases being attributed to injury of the brachial plexus. Since 1911, when the shoulder-joint injury was offered as the primary cause, this theory had made rapid progress. He thought it very probable that sufficient traction upon the head at birth to rupture the brachial plexus had never been applied in a successful delivery.

Dr. FRANCIS X. DERCUM felt there was the inclination to agree with Dr. Thomas regarding the nerve involvement which might be present as secondary to the trauma of the joint.

Dr. CHARLES W. BURR asked whether in Dr. Thomas' opinion anything should be done with the children at birth—whether anything could be done; or whether it was better to wait until the child was several months old before operating.

Dr. A. P. C. ASHHURST said that inquiry into the subsequent history of patients seen at the Orthopedic Hospital with birth injuries of the shoulder showed that they did not return because the parents believed that nothing could be done. In nearly all the cases there was persisting disability. With acceptance of Dr.

Thomas' theory there would be a change in the therapeutics and little further need of the neurologist in the cases. Obstetricians, he felt, ought to take more notice of the injury and prevent its recurrence. In several families in which such injury was present he had found that in one family three children had been severely injured at birth and the fourth killed at delivery. In another instance brothers and sisters had died at birth; in another, the sixth child only survived delivery. It was to be remembered also that these injuries did not all occur in difficult labors.

Dr. ALFRED GORDON regarded Dr. Thomas' advice and work perfectly satisfactory from the practical standpoint, and thought operation should be done as early as possible. In the matter of pathogenesis, however, he felt that he must differ with him. In the child presented by Dr. Thomas operation had been done early and there had been use of the arm for three and a half years; the type of atrophy present was such as was seen in typical muscular atrophy due to disease of the spinal cord and nerves, and he was inclined to believe that there was a real injury of the nerve trunks from the very beginning. In some cases there was found even a lesion of the cells of the spinal cord. Warrington was quoted as reporting 11 cases of complete recovery without operative procedure in a series of 32 cases; Bruns, 6 out of 11. Although instances were observed of adults in whom in infancy there had been brachial paralysis with recovery without operation, from a practical standpoint Dr. Gordon said he would follow the advice of Dr. Thomas in the matter of treatment.

Dr. THOMAS, in closing, said that all his work on the subject under discussion had been intended primarily to attract attention to the great need of recognizing the shoulder condition at birth and of correcting any displacement at that time. Evidence, he said, was being rapidly collected that the dislocation was present at birth. The only time when the joint displacement could be corrected was at birth. In the most severe cases the condition could be greatly improved at any stage, but it was never possible to restore the joint to the normal after many weeks. The greatest obstacle to the recognition of the dislocation was the failure to look for it, because of the general faith in the theory of a plexus rupture. The basic lesion, in his opinion, was the dislocation, anterior in adults, and posterior at birth. The cases without dislocation were merely those in which the same causal force was not severe enough to produce a dislocation, and stopped at a sprain. Dr. Thomas said that his observations upon the various phases of traumatic brachial palsies were rock-rooted in the work of the late Dr. G. G. Davis, professor of applied anatomy in the University of Pennsylvania, and his endeavor to carry some of the results of Dr. Davis' work on the cadaver over into surgical practice.

Conjugal Syphilis of the Nervous System.—Dr. ALFRED GORDON presented a review of disorders occurring in syphilitic affections of the nervous system, and gave a detailed account of 32 persons followed up for a number of years with various nervous disorders of syphilitic character. Not only wives and husbands, but other relatives—sisters, brothers, who cohabited with syphilitic parents, developed later in life neurosyphilis. In the latter case especially the question of hereditary syphilis was totally eliminated from the present series. The investigations proved of particular interest from the standpoint of prophylaxis.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

NORTH CAROLINA BOARD OF MEDICAL EXAMINERS.

Raleigh, 1919.

ANATOMY.

1. Describe the osteology of the head of the humerus. Name the muscles attached to it and describe one of them.

2. What structures would you cut in doing an amputation at the upper third of the femur?

3. Describe the portal circulation; what is the collateral circulation when the portal vein is blocked?

4. (*a*) Name the chambers of the heart. (*b*) The valves of heart and give their surface markings. (*c*) What is the nerve supply of the heart?

5. Give the branches of the common carotid artery.

6. Name the foramina at the base of the skull and the structures transmitted through each.

7. Discuss the anatomy of the uterus and vagina. What is the pouch of Douglas?

8. Give an anatomical description of the bronchial tubes.

9. Name and locate the ventricles of the brain. Where may the cerebrospinal fluid be normally found? How does it pass from the lateral ventricles to the cord?

10. Explain the following reflexes: (*a*) Pain in the region of the right shoulder in diseases of the liver and gall bladder; (*b*) rigidity of the abdominal wall in the acute inflammation of the appendix; (*c*) pain in the testicle during the passage of a stone from the kidney.

PHARMACOLOGY, MATERIA MEDICA, AND THERAPEUTICS.

1. What are fluid extracts? (*a*) How many grains of the drug would be required to make 1,000 c.c. of the fluid extract of aconite?

2. In what official preparation of digitalis do we find the diuretic principle?

3. How much strychnine in 10 c.c. of the tincture of nux vomica?

4. Name the official preparations of opium, with dose of each.

5. Give reason why the use of the tincture of iodine was discouraged as an antiseptic in front line first-aid work.

6. Name the antidote for poisoning by (*a*) strychnine, (*b*) opium, (*c*) phenol, (*d*) oxalic acid, (*e*) cocaine, and (*f*) arsenic.

7. What are the therapeutic uses of alcohol?

8. Give the treatment and prognosis of progressive pernicious anemia.

9. Define briefly but clearly (*a*) serum therapy, (*b*) antitoxin therapy, (*c*) prophylaxis.

10. Write a prescription for the following: (*a*) Influenza, (*b*) acute gastritis, (*c*) migraine, (*d*) sciatica, (*e*) cystitis.

11. Give briefly the treatment for sprue.

12. How can ophthalmia neonatorum be prevented and how treated?

CHEMISTRY AND HYGIENE.

1. What is inorganic chemistry? Organic chemistry? What element is a necessary component of all organic compounds?

2. In the purification of drinking water, describe distillation, filtration, precipitation. Which of these is absolutely safe and which is applicable to municipal supplies?

3. What is meant by a chemical antidote, with an example? What is meant by a physiological antidote, with an example?

4. What is the acid constituent of gastric juice? urine? and bile?

5. Give an approved method for determining the presence of glucose in urine. What disease condition does the presence of glucose indicate?

6. What are peptones and how are they produced? How do the albumins differ from peptones? Give a test for peptones.

7. Describe a chemical test for blood.

8. Describe the appearance of urea and uric acid, and give a chemical test for each.

9. What are the necessary hygienic conditions of a model sleeping-room floor area, height of walls, window area, and cubic air space to each occupant?

10. What diseases are preventable by timely administration of sera and vaccines?

PHYSIOLOGY, PATHOLOGY, AND BACTERIOLOGY.

1. (*a*) Explain briefly what is meant by nitrogen equilibrium. (*b*) Is it possible for one who is in nitrogen equilibrium to be gaining or losing in weight? Give reason for answer.

2. What danger may result from transfusion of blood from the veins of one animal to the veins of another, or from one individual to another? Explain cause.

3. Give briefly the pathology of round-cell sarcoma.
4. Describe the pathological changes that take place in acute endocarditis.
5. Give the pathology of gastric ulcer.
6. Name three parasitic fungi which are causes of diseases and the disease caused by each.
7. What are protozoa? Name a pathogenic protozoon. Outline laboratory method of examining for same.
8. Define amboceptor, anaphylaxis, bacterium, saprophyte, micron.

PRACTICE OF MEDICINE.

1. What diseases affect the pleura? Give physical signs; how would you differentiate?
2. Name and describe three varieties of angina.
3. What is the etiological factor in the production of scurvy?
4. Describe two varieties of leucemia.
5. What is the significance of an enlarged spleen? In what diseases do you find it enlarged?
6. What is the significance of occult blood in the stools?
7. Give symptoms of pyloric spasm; etiology; treatment.
8. What area of the brain is most often affected by cerebral hemorrhage?
9. Define delusion, hallucination.
10. Define briefly the etiology of eczema.

ANSWERS.

ANATOMY.

1. The *head of the humerus* is nearly hemispherical, and articulates with the glenoid cavity of the scapula; it is directed upwards and inwards. At the circumference of the head is a slight constriction, called the (anatomical) neck; this gives attachment to the capsular ligament, and is perforated by a number of vascular foramina. The greater tuberosity is situated on the outer side of the head; on it are three facets, giving attachment to the supraspinatus, infraspinatus, and teres minor muscles. The outer side of this tuberosity is rough, and is continuous below with the shaft of the humerus. The lesser tuberosity is in front of the head and is directed inwards and forwards. It presents a facet to which the subscapularis is attached. Between the two tuberosities lies the bicipital groove, in which are the long tendon of the biceps and a branch of the anterior circumflex artery.

The SUPRASPINATUS takes its *origin* from the supraspinous fossa of the scapula, and the aponeurosis which covers the muscle. It is *inserted* into the upper facet on the great tuberosity of the humerus, and is closely connected with the capsular ligament. The muscle is directed outwards and downwards, and the *nerve supply* is the suprascapular nerve (from the brachial plexus.)

2. *Structures severed in amputation of femur at upper third*—Skin, fascia, tensor vaginæ femoris, femoral artery and vein, profunda femoris (artery and vein), long saphenous vein and nerve, gluteal vessels, sciatic nerve, and the following muscles: Adductor longus, adductor brevis, adductor magnus, gracilis, semitendinosus, semimembranosus, biceps, gluteus maximus, sartorius, rectus femoris, vastus externus, vastus internus, crureus, and the femur.

3. By the *portal circulation* is meant the capillary circulation of venous blood in the liver, between the portal and hepatic veins.

Portal circulation: "The hepatic artery and the portal vein convey blood to the liver. The artery carries arterial blood, and the vein food-laden venous blood from the walls of the alimentary canal, and from the spleen and pancreas. Both vessels enter the liver at the transverse fissure, and they ramify in its interior, breaking up into small terminal branches which run between the lobules and send fine capillary branches into their substance; from these latter branches the blood passes into the capillary tributaries of the intralobular veins, thence to the sublobular veins, and from the sublobular veins to the hepatic veins, which terminate on the posterior surface of the liver in the inferior vena cava."—(Bain's *Medical Practice.*)

When the portal vein is blocked, collateral circulation may be carried on: (1) Between the superior hemorrhoidal vein and branches of the middle and inferior hemorrhoidal veins; (2) between branches of the gastric and esophageal veins; (3) between the superficial veins of the abdominal wall and the portal vein.

4. *The chambers of the heart* are: The left auricle, left ventricle, right auricle, and right ventricle.

The valves: The *aortic valves* are behind the third intercostal space, close to the left side of the sternum. *Pulmonary valves*, in front of the aortic, behind the junction of the third rib, on the left side, with the sternum. *Tricuspid valves*, behind the middle of the sternum, about the level of the fourth costal cartilage. *Mitral valves* behind the third intercostal space, about one inch to the left of the sternum.

The nerve supply of the heart: This is derived from the superficial and deep cardiac plexuses, with fibers from the vagus, spinal accessory and sympathetic nerves.

5. *Branches of the common carotid artery* are its two terminal branches, the external carotid and internal carotid. Occasionally it gives origin to the superior thyroid, inferior thyroid, ascending pharyngeal or vertebral artery.

6. FORAMINA AT THE BASE OF THE SKULL.—ANTERIOR FOSSA presents one single foramen and four in pairs:—*Foramen cæcum* transmits a small vein to the superior longitudinal sinus; *Ethmoidal fissure* transmits nasal branch of ophthalmic nerve; *Olfactory foramina*, for filaments of olfactory bulb; *Anterior ethmoidal* transmits anterior ethmoidal artery and nasal nerve; *Posterior ethmoidal* transmits posterior ethmoidal artery and vein.

MIDDLE FOSSA presents nine pairs:—*Optic foramen*, transmits the optic nerve and ophthalmic artery; *Foramen lacerum anterius*, or sphenoidal fissure, transmits third, fourth, three branches of the (third) ophthalmic division of the fifth, and sixth nerves, orbital branch of the middle meningeal, recurrent branch from the lacrymal artery, filaments of the sympathetic, and ophthalmic vein; *Foramen rotundum* transmits second division of fifth or superior maxillary; *Foramen Vesalii* transmits a small vein; *Foramen ovale* transmits third division of fifth or inferior maxillary nerve, small petrosal nerve, and small meningeal artery; *Foramen spinosum* transmits middle or great meningeal artery; *Foramen lacerum medium* transmits the internal carotid artery, carotid plexus, a branch of ascending pharyngeal artery, and the Vidian or large petrosal nerve: *Foramen* for lesser petrosal nerve; *Hiatus Fallopii* transmits petrosal branch of middle meningeal artery and petrosal branch of the Vidian nerve.

POSTERIOR FOSSA presents six pairs and one single one:—*Meatus auditorius internus* transmits auditory artery, facial and auditory nerves; *Aquæductus vestibuli* transmits small artery and vein and lodges a process of dura mater; *Foramen lacerum posterius*, or jugular foramen transmits inferior petrosal sinus and lateral sinus, forming the internal jugular vein, glossopharyngeal, pneumogastric, and spinal accessory nerves, and meningeal branches of ascending pharyngeal and occipital arteries; *Mastoid foramen* transmits small vein to the lateral sinus and small artery from occipital to the dura mater; *Anterior condyloid foramen* transmits meningeal branch from ascending pharyngeal artery and hypoglossal nerve; *Posterior condyloid foramen* transmits posterior condyloid vein; *Foramen magnum* transmits vertebral arteries, medulla oblongata and its membranes, and the spinal accessory nerves.—(From Young's *Handbook of Anatomy.*)

7. In the nulliparous adult the uterus is about three inches long, about two inches wide at the upper part, and about one inch thick. The uterus lies between the rectum behind and the bladder in front; it is below the abdominal cavity, and above the vagina. Its position is one of slight anteflexion, with its long axis at right angles to the long axis of the vagina. The anterior surface of its body rests on the bladder, and the cervix points backward toward the coccyx. The uterus is not fixed, but moves freely within certain limits. It is held in place by ligaments. (1) *Broad ligaments*, which extend outward on each side from the side of the uterus to the side of pelvis. (2) *Rectouterine ligaments*, which extend backward from the intraperitoneal portion of the cervix uteri to the peritoneal investment of the rectum. (3) *Round ligaments*, which extend from

the uterus just below the Fallopian tubes, through the inguinal canal to the labia majora. (4) The *ovarian ligaments*, which extend from the superior part of the uterus, behind the Fallopian tubes, to the inner end of the ovary. (5) The *uterosacral ligaments*, which extend from the highest part of the cervix uteri to the sides of the sacrum opposite the lower border of the sacroiliac synchondrosis.

The *vagina* extends from the vulva to the uterus, lying behind the bladder and in front of the rectum; the anterior and posterior surfaces are in apposition; the anterior wall is about 3½ in. long, and the posterior wall about 4½ in. Above, it embraces the cervix of the uterus.

The *pouch of Douglas* is a recess formed by the peritoneum between the rectum and the upper part of the posterior wall of the vagina; it corresponds to the rectovesical pouch in the male.

8. *The bronchial tubes:*—"The bronchi divide and subdivide, in the substance of the lungs, into a number of smaller and smaller branches (bronchial tubes), which penetrate into every part of the organ, until at length they end in the smaller subdivisions of the lungs called *lobules*. All the larger branches have walls formed of fibrous tissue, containing portions of cartilaginous rings, by which they are held open, and unstriped muscular fibers, as well as longitudinal bundles of elastic tissue. They are lined by mucous membrane the surface of which, like that of the trachea, is covered with ciliated epithelium, but the several layers become less and less distinct until the lining consists of a single layer of short columnar cells covered with cilia. The mucous membrane is abundantly provided with mucous glands. As the subdivisions become smaller and smaller, and their walls thinner, the cartilaginous rings become scarcer and more irregular, until, in the smaller bronchial tubes, they are represented only by minute and scattered cartilaginous flakes. When the bronchial tubes, by successive branchings, are reduced to about 1/40 of an inch in diameter they lose their cartilaginous element altogether, and their walls are formed only of a fibrous elastic membrane with circular muscular fibers; they are still lined, however, by a thin mucous membrane with ciliated epithelium, the length of the cells bearing the cilia having become so far diminished that the cells are now cubical. In the smaller bronchial tubes the muscular fibers are relatively more abundant than in the larger ones, and form a distinct circular coat. . . . On entering a lobule, the small bronchial tube divides and subdivides; its walls at the same time become thinner and thinner, until at length they are formed only of a thin membrane of areolar, muscular, and elastic tissue, lined by a layer of pavement epithelium not provided with cilia. At the same time they are altered in shape; each of the minute terminal branches widens out funnelwise, and its walls are pouched out irregularly into small saccular dilatations, called air-sacs. Such a funnel-shaped terminal branch of the bronchial tube, with its group of pouches, or air-sacs, is called an infundibulum, and the irregular oblong space in its center, with which the air-sacs communicate, an intercellular passage."—(Halliburton.)

9. There are five ventricles of the brain. The *two lateral ventricles* are situated one in each cerebral hemisphere; the *third ventricle* is situated in the middle line, between the two optic thalami; the *fourth ventricle* is the expanded portion of the central canal of the spinal cord; it is a diamond-shaped cavity situated between the cerebellum behind, and the posterior surface of the pons and medulla in front. The *fifth ventricle* is between the two layers of the septum lucidum. Cerebrospinal fluid may be normally found in the ventricles of the brain, in the central canal of the spinal cord, and in the subarachnoid space.

The cerebrospinal fluid passes from the lateral ventricles through the foramen of Monro into the third ventricle; then through the aqueduct of Sylvius (or iter a tertio ad quartum ventriculum) into the fourth ventricle, through the latter, and into the central canal of the spinal cord.

10. *Pain in the region of the right shoulder in diseases of the liver and gall bladder* is transmitted from the latter by way of the right phrenic nerve to the fourth cervical nerve, thence to the supraacromial nerve.

Rigidity of the abdominal wall in acute inflammation of the appendix is due to the fact that the same nerves which supply the peritoneum supply also the abdominal muscles and the skin which overlies them.

Pain in the testicle during the passage of a stone from the kidney is due to the fact that there is a communication between the renal plexus and the spermatic plexus.

PHARMACOLOGY, MATERIA MEDICA, AND THERAPEUTICS.

1. *Fluid extracts* are concentrated solutions of vegetable drugs, of such strengths that one cubic centimeter of the fluid extract represents one gram of the drug; or one minim of the fluid extract represents one grain of the drug.

One thousand grams (=15,432½ grains) of aconite are required to make 1000 c.c. of the fluid extract of aconite.

2. The diuretic principle of digitalis is found in the Infusion of Digitalis.

3. In 100 c.c. of tincture of nux vomica, there is 0.1 gram of strychnine; therefore in 10 c.c. of tincture of nux vomica, there is 0.01 gram of strychnine.

4. OPIUM. *Official preparations, with doses:* Powdered opium, gr. j; extract of opium, gr. ss; powder of ipecac and opium, gr. vijss; deodorized tincture of opium, ♏viij; granulated opium, gr. j; morphine, gr. ⅛, morphine sulphate, and hydrochloride, each gr. ⅛; codeine, gr. ½; codeine sulphate, gr. ½; apomorphine hydrochloride, gr. 1/10.

5. *Tincture of iodine in front line first-aid work:* "In general the results as regards the prevention of sepsis have been disappointing, mainly it would appear because the injured man is not apt in most cases to put the iodine where it can reach the focus of infection. The presence of much blood and prolonged oozing are, of course, inimical to the exercise of germicidal action. Usually little more is accomplished than a fair cleansing of the adjacent skin."—(Dakin and Dunham's *Handbook of Antiseptics*).

6. *Antidote for strychnine*, potassium permanganate; for *opium*, potassium permanganate; for *phenol*, syrup of lime; for *oxalic acid*, calcium chloride or lactate; for *cocaine*, tannin; for *arsenic*, ferric hydrate with magnesia.

7. *Therapeutic uses of alcohol:*—"Alcohol is employed as an evaporating lotion for sprains, bruises, and local inflammations, and its rubefacient and astringent effects are also made use of in various conditions. Given internally, it may relieve gastric pain and is sometimes of service in checking nausea and vomiting. It is useful in diarrheal affections and in intestinal as well as gastric colic. Alcohol is of immense advantage in many cases of febrile disease, when during critical periods it sustains the vital powers by supplementing the insufficient quantity of nutriment which the system is capable of appropriating and at the same time stimulating the digestion, and thus enabling the patient to dispose of an increased amount of food. It is also highly useful in arousing and supporting the flagging powers in sudden depression of the system, as in shock, syncope, severe hemorrhage, and poisoning by various drugs. In carbolic acid poisoning and snakebite it likewise has a direct antidotal effect. In certain chronic conditions it is of undoubted benefit, but the danger of the patient's contracting the alcoholic habit must always be taken into consideration."—(Wilcox's *Materia Medica.*)

8. *Treatment of pernicious anemia:* "Fresh air, rest and a diet as liberal as the digestive powers of the patient will permit are requisite. Warm salt baths and massage are valuable adjuvants to internal treatment. The teeth should receive careful attention. If there be gingivitis or pyorrhea alveolaris, antiseptic mouthwashes should be used at frequent intervals. Arsenic is the most valuable drug. It may be given in the form of Fowler's solution, the dose being gradually increased from 2 or 3 to 15 or 20 minims three times a day. Iron is rarely of service. Bone-marrow is sometimes efficacious. Inhalations of oxygen have been recommended. Appropriate anthelmintic remedies should be given, of course, in the cases in which intestinal parasites are present. Digestive disturbances are often benefited by diluted hydrochloric acid and a bitter."—(Stevens.)

The *prognosis* is very unfavorable, most cases ending fatally.

9. "*Serum-therapy proper* is the prophylactic and curative treatment of certain infectious diseases by the subcutaneous or intravenous administration of a blood-serum containing an antibody (antitoxic, bactericidal, etc.) which is specific to the particular disease. As generally used, however, the term includes also the treatment of some of these affections by vaccines and by the toxic products (toxins) of attenuated cultures of their respective microbes; but these toxins, though sometimes grown on blood-serum, may be produced on other media, and are never administered in a blood-serum, as the antibodies invariably are."—(Potter's *Materia Medica.*)

Antitoxin therapy is the use of antitoxins for the prevention and cure of certain specific diseases (such as diphtheria and tetanus).

Prophylaxis is the prevention of a disease by any means.

10. *For influenza:*

℞ Acetphenetidini
Phenylis salicylatis āā.....gr.lx
Misce et divide in chartulas .....No. xij
Signa: Take one powder every three hours.

For acute gastritis:

℞ Bismuthe subnitratis 3iij
Acidi hydrocyanici diluti .....♏ xxxij
Aquæ q. s. ad.....℥iv. Misce
Signa: One dessertspoonful every three hours.

For migraine:

℞ Caffeinæ citratæ .....gr. xij
Acetphenetidini .....gr.ix
Sodii bromidi .....3j. Misce
Fiant chartulæ .....No. xij
Signa: Take one powder every two or three hours.

For sciatica:

℞ Morphinæ sulphatis .....gr. ij
Atropinæ sulphatis .....gr. 1/15
Tincturæ aconiti .....♏ x
Fluidextracti cannabis indicæ.....♏ xxv
Elixiris aurantii .....℥j. Misce
Signa: Take one teaspoonful every three or four hours until relieved.

For cystitis:

℞ Tinturæ aconiti 3iij
Spiritus ætheris nitrosi.....℥j
Liquoris potassi citratis q. s. ad.....℥vj. Misce
Signa: Take one dessertspoonful every four hours while there is any fever.

11. *Treatment of sprue:* "It is essential that the patient possess the will power to carry out the course of treatment; the clothing should be of wool to prevent chilling and the patient should remain in bed until his condition has decidedly improved.

"*The milk treatment:* A preliminary dose of castor oil is given and when this acts the patient should begin taking milk as the sole food. At first about 4 pints of skimmed milk are given daily. The milk should be given in two-hour feedings, well warmed and taken through a glass tube or with a teaspoon—it should not be drunk. As the stools become less frothy the amount of milk is increased so that the patient takes from 6 to 7 pints daily. Milk should be the sole food for six weeks from the time the stools become solid and the mouth symptoms disappear. Eggs are usually well borne after the milk course. Stale bread or toast is cautiously added and then some fish or chicken.

"At times the patient seems benefited by giving a meat treatment day once or twice a week during the course of the milk treatment.

"*Meat treatment:* If the patient is very ill it may be advisable, after the preliminary dose of castor oil, to give meat juice obtained by expressing the juice from slightly broiled meat, about 2 teaspoonfuls every half hour. If possible however one starts in with the meat cure, which is about 4 ounces of a lightly broiled chopped up beefsteak, every four hours. Raw meat is usually given in this treatment but there is danger of *T. saginata* infection.

"At least 4 pints of warm water should be taken daily but not at the same time the patient eats the meat. Rest in bed and the avoidance of chilling are important measures.

"The only drug that has been advocated to any extent is santonin, in doses of 5 grains, night and morning. It is very doubtful if any drug treatment is of the least value."—(Stitt's *Tropical Diseases.*)

12. Ophthalmia Neonatorum. *Prophylaxis:* Whenever there is the possibility of infection, or in every case, wash the eyelids of the newborn child with clean warm water, and drop on the cornea of each eye one drop of a 1 per cent. solution of nitrate of silver, immediately after birth. *Treatment:* Wash the eyes carefully every half hour with a saturated solution of boric acid; pus must not be allowed to accumulate. Two drops of a 2 per cent. solution of nitrate of silver must also be dropped on to the cornea every night and morning. The eyes must be covered with a light, cold, wet compress. The patient must be isolated, and all cloths and compresses used must be burnt.

CHEMISTRY AND HYGIENE.

1. *Inorganic chemistry* is that branch of chemistry which deals with inorganic substances (that is substances which do not contain carbon).

Organic chemistry is the chemistry of carbon and its compounds.

Carbon is a necessary component of all organic compounds.

2. *Distillation* consists in boiling the water and condensing the steam again to a liquid.

Filtration consists in removing the suspended impurities by passing the water through a porous material such as sand, charcoal, or unglazed porcelain.

Precipitation consists in removing impurities by mechanically carrying them down; they "settle" when the water is left at rest. Alum or a ferric salt is generally used.

Distillation is absolutely safe; and *filtration* is applicable to municipal supplies.

3. Antidotes are classified as: (1) *Chemical antidotes*, which act by uniting chemically with the poison and thus converting it into a harmless or insoluble compound. *Example:* Albumin, in mercurial poisoning; sodium sulphate, in carbolic poisoning.

(2) *Physiological antidotes*, which act by combating one (or more) of the physiological actions of the poison. *Example*: Opium will counteract the dilated pupil caused by belladonna.

4. The *acid constituent* of *gastric juice* is hydrochloric acid; of *urine*, is acid sodium phosphate; of *bile*, is glycocholic acid and taurocholic acid.

5. *Fehling's test for sugar in the urine:* Place in a test-tube a few c.c. of the liquid prepared as stated below, and boil; no reddish tinge should be observable, even after five minutes' repose. Add the liquid under examination gradually, and boil after each addition. In the presence of sugar a yellow or red precipitate is formed. In the presence of *traces* of glucose, only a small amount of precipitate is produced, which adheres to the glass, and is best seen when the blue liquid is poured out.

[The reagent must be kept in two solutions, which are to be mixed immediately before use. Solution I consists of 34.653 gms. of crystallized $CuSO_4$, dissolved in water to 500 c.c.; and solution II of 130 gms. of Rochelle salt dissolved to 500 c.c. in NaHO solution of sp. gr. 1.12. When required for use equal volumes of the two solutions are mixed, and the mixture diluted with four volumes of water.]

Significance of sugar in the urine: Diabetes mellitus; brain lesions involving the floor of the fourth ventricle; cerebral tumors and hemorrhages; some nervous diseases, sciatica, tetanus; certain hepatic disorders; pneumonia, typhoid, or some febrile disease, particularly during convalescence; after ingestion of chloral, morphine, and some other poisons.

6. *Peptones* are derived proteins, of smaller molecules than the proteoses; they are produced during peptic and tryptic digestion. They consist of polypeptides, and are usually considered to be the end product of the action of pepsin upon protein material; but they may be split up in polypeptides and amino-acids.

Peptones are not coagulated by heat, are precipitated but not coagulated by alcohol, are not precipitated by nitric acid or ammonium sulphate, and are diffusible.

Albumins are coagulated by heat, are precipitated and then coagulated by alcohol, are precipitated by nitric acid and by ammonium sulphate, and are not diffusible.

Test for Peptones: Peptones give the biuret reaction, and are precipitated by phosphomolybdic acid. And see above.

The best chemical test for blood, is the formation of hemin crystals. These crystals are obtained by boiling a fragment of dried blood with a drop of glacial acetic acid on a slide; the characteristic crystals may be seen with the microscope.

8. *Urea* is a transparent, crystalline solid; it is soluble in water and in alcohol, neutral in reaction; under the influence of heat it evolves ammonia and ammonium carbonate; biuret is at first produced, this (dissolved in water) gives a red-violet color with potassium hydroxide and cupric sulphate (biuret reaction). Urea is decomposed by the alkaline hypobromites, the products being a bromide, water, nitrogen, and carbon dioxide.

Uric acid is a crystalline solid, occurring in colorless plates or prisms; it is sparingly soluble in water; it is tasteless and odorless; its aqueous solution is acid to litmus; it dissolves in solutions of KOH and NaOH, with formation of urates; it is decomposed by heat, and by sodium hypobromite.

Murexide Test for Uric Acid: If a little dilute nitric acid is added, and evaporated to dryness, a yellowish-red residue is left; if a little ammonia is now added, a violet color is produced (in the presence of uric acid).

9. The sleeping-room should be as large as possible, with the maximum of sunshine and fresh air; it should face the south, or east, or southeast, and should contain no hangings, and have as few "dust-catching" contrivances as possible; it should not lead into a bath-room. The floor area should be at least 70 to 80 square feet; the walls should be 9 or 10 feet high; the window area should be not less than one-tenth of the floor space, and one-fifth would be better; the cubic air space should be from 1,000 to 2,000 cubic feet for each person.

10. *Diseases which may be prevented by the timely administration of sera and vaccines*: Diphtheria, tetanus, typhoid, plague, cholera, smallpox, rabies.

PHYSIOLOGY, PATHOLOGY, AND BACTERIOLOGY.

1. *Nitrogen equilibrium* is the condition existing when the amount of nitrogen excreted exactly equals the amount ingested.

A person may be in nitrogen equilibrium and yet may gain or lose weight, because the carbon equilibrium does not necessarily accompany the nitrogen equilibrium.

2. "*Transfusion* is the transmission of blood from an artery of one person to the vein or artery of another. It requires careful technique, involves the willingness of a second person to contribute blood, and is not free from danger. The dangers are: (1) Clotting; (2) the transmission of disease, such as syphilis; (3) the collapse of the donor of the blood, and (4) hemolysis. Before transfusion the blood of the donor should be tested with that of the patient for fear of hemolysis. This is especially likely to occur in infants or in the presence of a malignant tumor (Crile). By recent improved methods the clotting and technical difficulties have been much reduced, so that transfusion, which was at one time abandoned, has again come into general use. The artery of the donor is usually connected with a vein of the recipient by some apparatus, and the blood allowed to flow gently for fifteen or twenty minutes, or until the donor begins to show the effects of loss of blood. In some cases transfusion into an artery brings a more prompt response than into a vein. For in transfusion into a vein the transfused blood may merely increase the volume of the already excessive venous blood, and in any case must pass to the right heart and through the pulmonary circulation before the left heart can act upon it; while by transfusion into an artery the new blood, owing to the increased peripheral resistance, stimulates the heart and invigorates the coronary circulation."—(Bastedo's *Materia Medica.*)

Dangers of transfusing blood from lower animals to man: "The serum of certain animals possesses the property of dissolving the red corpuscles of another species of animals. The serum of a dog destroys the red corpuscles of a man; the hemoglobin is dissolved out. The serum, besides its action on the red corpuscles, is also active against the white corpuscles of the same animal, stopping their ameboid movements. The globulicidal action of the serum is related to its poisonous action on microbes. The normal serum of certain animals kills microbes, as the serum of the dog kills the typhoid bacilli. The power to kill red corpuscles and microbes is due to the presence in the serum of a substance, an alexin. In transfusion this plays an important part."—(Ott's *Physiology.*)

3. *Round-celled sarcoma:*—"There are two classes. (1) The *small round-celled sarcomata* consist of cells of about the size and appearance of mononuclear leucocytes, and may have much or little intercellular substance, which may be irregularly disposed or arranged in large meshes resembling alveoli. In many cases, so small is the quantity of intercellular substance that it is difficult of detection without special modes of preparation. These tumors often contain many blood-vessels and may be very soft and succulent. Their growth is sometimes rapid and they are often very malignant. They most frequently occur in the connective tissue of the muscles and fasciæ, in bone, and in lymph nodes. They also occur in the internal organs, not infrequently in the brain and retina, associated with cells of the glia type. Whether all the small round cells are glia cells or whether there is a mixture of cells is not yet fully determined. Such tumors are generally designated *gliosarcoma.* (2) In the *large round-celled sarcomata,* the cells vary in size, but are usually very much larger than in the last variety. Their nuclei are usually large and contain prominent nucleoli. They, too, are often very vascular, and contain a variable quantity of basement substance. They are occasionally alveolar in character. They are, as a rule, less soft and malignant than the small-celled varieties."—(Delafield and Prudden's *Pathology.*)

4. ACUTE ENDOCARDITIS. *Morbid anatomy:* In the simple form there will be found a cloudiness, followed by edematous thickening of the valvular endocardium; superficial erosions, and the formation of small granulations; deposits of layers of fibrin and corpuscles from the blood, the whole process resulting in the formation of small warty vegetations. These vegetations are most marked at a slight distance from the free borders of the valves—*i. e.* those parts which come into apposition during closure. In course of time they are transformed into fibrous tissue. According to Poynton and Paine the infective organisms are conveyed to the base of the valves by the capillaries, and thence pass to the subendothelial tissues by the minute nutrient channels in the valvular substance; others hold that the organisms are derived from the blood circulating over the surface of the valves. In the malignant form the initial changes are similar, but there are some important differences, inasmuch as ulcerations may completely replace the vegetations. The differences are: (1) The vegetations when present are larger and fungating. (2) The underlying tissues are necrotic and show loss of substance and round-celled infiltration. (3) They contain masses of micrococci, while in simple endocarditis the organisms are scanty. The two forms cannot be distinguished by the organisms producing them; either simple or malignant endocarditis may arise from a pyogenic infection. (4) When the vegetations become detached they form *septic* emboli, giving rise to metastatic abscesses. (5) The ulcerative process causes great destruction of the valves, and may even lead to perforation of the curtains. (6) The subsequent or permanent changes in the valves, if the patient survives, are much more marked. (7) If the vegetation touches the mural endocardium as it flaps to and fro, the part touched becomes affected by contact.

As regards the side of the heart most affected—*congenital* endocarditis attacks the right side of the heart (but note that many congenital cardiac lesions are due not to endocarditis, but to developmental faults); simple endocarditis attacks the left only; the *malignant* attacks *both sides,* though the *left* is much more implicated than the right side.

The vegetations are upon that side of the valve opposed to the blood-stream—viz., at the aortic valve the vegetations project into the ventricle, at the mitral valve into the auricle.

As in pericarditis, the myocardium almost always

shares in the inflammatory affection.—(Wheeler and Jack's *Practice of Medicine.*)

5. GASTRIC ULCER—*Pathology:* "Peptic ulcers may be single, but are more often multiple. They are commonly situated in the lesser curvature and the posterior wall of the stomach, near the pylorus; occasionally they are found at the fundus or at the cardiac end. They vary in diameter from a few millimeters to three or five centimeters. Their shape is characteristic in that they have sloping edges giving them a funnel-form, with the apex toward the muscular coat. The edges may be irregular and rough, but are often, especially in older ulcers, quite smooth and rounded. Two dangers are always imminent, hemorrhage and perforation. Constant oozing of blood may be due to erosion of the surface, and larger hemorrhages may result from ulceration of one of the larger arterial branches of the stomach. Perforation is less common than hemorrhage. When the ulcer is situated posteriorly perforation is prevented by adhesions attaching the stomach to the head of the pancreas or other structures. When the ulcer is in the anterior wall perforation is more liable to take place. The rupture may occur into the peritoneal cavity or into any of the surrounding structures and fistulous communications may be established with the pleural or pericardial cavities, or even with the exterior through the abdominal walls. Abscesses of the liver, spleen, or pancreas may result from perforation into these organs. In the healing of the ulcers scars are formed in the wall of the stomach. These have usually a rather characteristic stellate shape. In case of large ulcers extensive scars and considerable construction of portions of the walls of the stomach result. Hour-glass contraction of the organ, or pyloric stenosis, may follow, and secondary changes, such as gastric dilatation, may ensue. Carcinomatous transformation is a not infrequent result of long-standing ulceration." (Stengel's *Pathology.*)

6. PARASITIC FUNGI: (1) *Tricophyton,* which causes ringworm; (2) *Achorion schonleini,* which causes favus; (3) *Discomyces bovis,* which causes actinomycosis.

7. *Protozoa* are unicellular animal organisms.

The *plasmodium malariæ* is a protozoon.

In examining for malaria: "Prepare some perfectly clean and very thin cover slips, and remove all traces of grease. Cleanse the skin of the finger-tip or ear with soap and water, and then with alcohol and ether. Make a *small prick* in the skin. Wipe away the first drop of blood, leaving a perfectly dry surface, so that subsequent drops will not run. Squeeze out a tiny drop about the size of a large pin's head. Touch the apex of this drop with the center of a cover glass, and immediately drop it, face downward, on a perfectly clean slide. Make several such preparations, and reject all those in which rouleaux are present. It is absolutely essential that the red corpuscles should lie flat. Examine with a 1/12 immersion lens and rather feeble illumination. Look in the red corpuscles for the presence of small black specks, often rod-like and showing slow movements of translation. These are surrounded by clear areas. One may also see in the center of some of the red cells clear ameboid areas which show no pigment. Rosette forms may also be visible. These forms of the parasite are always present in cases of malaria which have not had quinine. Other varieties are only met with in some chronic cases. Of these there are two chief forms: (1) The crescentic, (2) the flagellated. These are easily recognized. The crescentic bodies are highly refractile, rather longer than a red blood corpuscle, and about 2μ in diameter. Particles of pigment may be recognized in the parasite and also in some of the ordinary leucocytes."—(Hutchinson and Rainy.)

8. *Amboceptor* is an antibody having a double combining affinity, one linking on to the cell to be destroyed and the other linking on to the alexin or complement.

Anaphylaxis is a condition of supersensitization induced by the injection of a serum. It is the opposite of prophylaxis, and in place of rendering the person injected immune, the serum has made him particularly susceptible.

Bactcrium is a unicellular vegetable organism, devoid of chlorophyl, and dividing by fission.

Saprophyte is a bacterium which thrives best on dead organic matter.

Micron is the one-thousandth part of a millimeter; it is the unit of measurement in microscopical work.

PRACTICE OF MEDICINE.

1. *Diseases which affect the pleura* are: Pleurisy, empyema, hydrothorax, and pneumothorax.

Physical signs of pleurisy: Inspection during the early stages shows deficient movement of the affected side. After the effusion has formed there will be observed bulging of the affected side, with obliteration of the intercostal spaces and displacement of the cardiac impulse. *Palpation* demonstrates feeble, or absence of, vocal fremitus over the effusion, with exaggeration of the same above the fluid. The affected side is immobile, and very rarely fluctuation may be obtained. *Percussion* during the early stage yields a slightly impaired note. Later, dullness or even flatness, with increased resistance may be obtained directly over the fluid, while above the effusion and percussion-note is tympanitic. The line of demarcation is higher behind than in front. Effusion of the left pleural cavity obliterates Traube's semilunar space. The fluid changes its level with different positions of the body and the area of dullness is correspondingly movable.

Auscultation reveals during the early stage a feeble vesicular murmur over the affected side. A friction sound, slight and creaking, becoming louder as the exudation of lymph increases, limited usually to the angle of the scapula of the affected side, rarely over the entire side, accompanies the respiratory movements. During the stage of effusion, the vesicular murmur is feeble or absent on the affected side. Above the effusion, puerile breathing is heard, and just at the upper margin of the fluid a friction sound may be heard. Vocal resonance is diminished or absent over the fluid and markedly increased above the effusion, egophony being obtained at its upper margin. With the absorption of the fluid, the vesicular murmur and the moist friction sound gradually return.

Physical signs of hydrothorax are those of pleural effusion.

Physical signs of *empyema* are those of fluid in the pleural cavity, the affected side does not move on respiration, the percussion note is dull, there is absence of breath sounds, and vocal resonance and fremitus are diminished.

Physical signs of pneumothorax: Inspection shows enlargement of the affected side, with absent or diminished respiratory movements. The intercostal spaces are widened. The apex beat is displaced. *Palpation* reveals diminished tactile fremitus. *Percussion* yields marked changes in the resonance. Immediately after the rupture, the percussion note is hyperresonant, or even tympanitic or amphoric in quality. If the amount of air in the pleural cavity becomes extreme, there is dullness on percussion, associated with a feeling of great resistance or density. When effusion of blood occurs, dullness is obtained over the lower part of the chest, hyperresonant, or tympanitic percussion-note over the upper portions of the chest, these sounds changing as the patient changes position. *Auscultation:* The normal vesicular murmur may be diminished or absent. The typical amphoric respiratory sound is heard when the fistula is open. The vocal resonance may be diminished or absent, or, rarely, it may be exaggerated, with a distinct metallic echo.—(From Hughes's *Practice of Medicine.*)

The differentiation can be made mainly by the physical signs; but in addition in *empyema* there will be found fever, chills, leucocytosis and presence of pus on aspiration; in *hydrothorax,* serous fluid will be found on aspiration.

2. THREE VARIETIES OF ANGINA: (1) *Angina pectoris,* characterized by sharp, agonizing pain, extending from the heart to the neck and down the left arm; shortness of breath, an anxious expression, and fear of impending death are prominent symptoms.

(2) *Ludwig's angina* is an inflammation of the floor of the mouth and the structures of the side of the neck, accompanied by pain, swelling, dysphagia, and constitutional symptoms; it is probably a streptococcus infection.

Vincent's angina is a sore throat caused by the fusiform bacillus and also by the *Spirochæta darticola;* it resembles diphtheria, from which it is differentiated by taking a smear and making a culture. .

3. *Etiology of scurvy:* Deficiency of fresh vegetables in the diet, lack of vitamines, unhygienic surroundings and mental depression have all been urged as etiological factors.

4. *Leukemia* is a condition in which there is a great and persistent increase in the number of white blood corpuscles. There are two varieties of the disease: (1) *Splenomedullary* in which the chief changes are found in the spleen and bone marrow; and (2) *lymphatic*, in which the chief changes occur in the lymphatic glands. In *splenomedullary leukemia*, there is an enormous leucocytosis, and myelocytes are present. In *lymphatic leukemia*, the lymphocytes form the main part of the leucocytosis, and there are no myelocytes.

5. ENLARGEMENT OF THE SPLEEN. *Excessive chronic enlargement* is most frequently due to leukemia, splenic anemia or chronic malaria; lesser degrees may be met with in cirrhosis of the liver, rickets, pernicious anemia, passive congestion, or actual portal obstruction. *Acute enlargement* is most often encountered in septicemia, malarial fever, typhoid and typhus, erysipelas, acute miliary tuberculosis, tuberculous peritonitis, cerebrospinal meningitis, smallpox, diphtheria, scarlet fever, relapsing fever, infarct, plague and certain other tropical diseases.—(Greene's *Medical Diagnosis.*)

6. *Occult blood in the stools* may be found in cases of malignant tumors of any part of the gastrointestinal tract, gastric ulcer, pancreatitis, catarrhal jaundice, and intestinal parasites.

7. PYLORIC SPASM. *Etiology:* It is usually due to some severe irritation of the mucosa of the pylorus, such as that produced by the acid in superacidity or supersecretion; or it may be due to an ulcer, erosions, fissures or cancer at the pylorus, while there are other forms entirely of nervous origin. *Symptoms:* At the height of digestion the pylorus suddenly becomes spasmodically contracted with intense pain in its region, together with eructations and often vomiting. At first the spasm appears periodically, but as the disorder progresses it may become continuous and produce a spastic contraction of the pylorus, with tendency to dilatation and retention of food. The food is vomited under these conditions, and possesses all the characteristics of that observed in a dilated stomach. Relief is afforded by the vomiting for a period of time varying from one to three or four days, when the same disturbance is again produced. The symptoms found in dilatation are then observed—emaciation, intense thirst, and constipation. *Treatment:* This consists primarily in properly looking after the underlying neurasthenia. For this purpose change of scene, massage, electricity, or a rest cure, may be found advisable. The diet should be carefully regulated, all irritating foods being avoided, and the meals should be small, easily digested, and given at regular intervals. The administration of olive oil has been found of great service. When retention is present, gastric lavage with plain water or nitrate of silver solution must be given. For the pain codeine combined with belladonna is serviceable; hot applications to the abdomen and a thorough lavage usually afford most relief from the pain. Dilatation of the pylorus, pyloroplasty, and gastroenterostomy have all been recommended.—(From Osler and McCrae.)

8. *Cerebral hemorrhage* most commonly affects the internal capsule, corpus striatum and optic thalamus.

9. A *delusion* is a belief in something which has no real existence, but is purely imaginary, and out of which the person cannot be reasoned. An *illusion* is a false or perverted impression, received through one of the senses. An *hallucination* is the same as an illusion, but without any material basis.

If an individual believes himself to be made of glass, and is afraid of being touched lest he be broken, he is suffering from a *delusion.* If the whistling of the wind is mistaken for a voice telling a person to do a certain thing, that would be an *illusion.* If a person fancied he heard a voice when there was nothing at all to be heard, that would be an *hallucination.*

10. *Etiology of eczema.* Eczema is believed to be due to digestive disturbances, local irritants (mechanical, chemical, or thermic), absorption of toxins, constipation, gout, rheumatism, nervous disturbances, diabetes, nephritis, and other diseases. Many of these diseases are only *predisposing* causes.

Miscellany.

Early Spanish Medical Journalism.—In *El Siglo Médico* for April 10, Cortezo Collantes discusses this subject and incidentally covers the periodicals which were current before the first appearance of *El Siglo Médico* in 1853. In 1734 there appeared a monthly entitled *Barometrico-Medical Ephemerides,* as the organ of the recently organized Academy of Medicine and Surgery. During the 120 years which elapsed up to the first appearance of *El Siglo* probably a hundred medical periodicals were initiated. For the thirty years which followed the first appearance of *El Siglo* an additional sixty-three periodicals must be added. Any attempt to digest this periodical material must fall short of the real facts. Various centers of education and progress were represented. Barcelona, Seville, Cadiz, Malaga, in addition to Madrid, were the pioneers in this field. The other university towns are not cited in this connection, so that the great number of new periodicals originated in a few towns. In addition to those already mentioned, periodicals were started at Valencias, Badajoz, and other less known places, but these were unimportant and shortlived. As a matter of fact, Madrid and (to a less extent) Barcelona gave birth to nearly all of the periodicals, which started under the same auspices. Just as all of the previous attempts to found a permanent Spanish journal culminated in *El Siglo Médico,* so the status of this periodical made all possibility of rivalry uncertain. *El Siglo Médico* appears to represent a consolidation of *El Boletin de Medicina, Cirugia y Farmacia,* and the *Gaceta Médica.*

Monument to French Military Surgeons.—At a recent session of the Rio de Janeiro Academy of Medicine a subscription was opened for funds for the erection of a proposed monument in Paris to the French medical men who lost their lives while on duty in the great war. Commenting on this fact the editor of *El Siglo Medico* deplores that no such action has been forthcoming in honor of Spanish medical men who have given their lives to their country in the Spanish colonies, past and present. At the present moment Spanish physicians are distinguishing themselves by lives of heroism in exotic fields. One only of them has received a decoration.

American Style All-Night Drug Store in the Gulf of Corinth.—Three American girls, Miss Julia Norton, of South Orange, N. J.; Miss Mary Vanneman, of Springfield, Mass., and Miss Constance Horsford, of Boston, all members of the American Red Cross Commission of Greece, conducted for a time the only all-night drug store in Europe. They were sent to the Island of Aigon, in the Gulf of Corinth, to take care of 1,300 Greek refugees from Bulgarian concentration camps and who were put off the steamer at Aigon to recuperate before being sent to their homes. As a twenty-four hour service seemed necessary in order to care for these sick and miserable Greeks, the girls decided to start a drug store and dispensary and to run it American style, open day and night. For a time they worked at top speed, feeding and cleaning up the refugees, among whom skin diseases were very prevalent.

THE EMPATHIC INDEX AND PERSONALITY.*

BY A. A. BRILL, PHB., M.D.,
NEW YORK.

IDENTIFICATION as found in dreams and neurotic symptoms, especially in fancies, is well known. According to Freud,[1] "through identification the patients are able to represent not only their own experiences but the experiences of a great many persons; they can suffer, as it were, for a whole mass of people and fill all the parts of a drama by means of their personality alone." One can best observe identification in the socalled *folies à deux*. Here one finds on deep investigation that it is not just an imitation. It is, as Freud puts it, "a sympathy based upon the same etiological plane." It expresses itself in an "as though" and refers to the same qualities which have remained in the unconscious. Let me cite an example:

Mrs. Love, a widow of forty-five years, showed a paranoid type of reaction; she was delusional and hallucinatory, most of her ideas were centered around spiritualism. Spirits communicated with her, she heard peculiar voices and significant knockings on the wall; she could even see the spirits and communicate with them. The whole system was erotically tinged; she had many somatic delusions referable to the genitals and maintained that they were produced by a spirit who was in love with her. She described this spirit as a very distinguished nobleman of the Middle Ages; she was not sure of his name but it was something like "Gandini." Her older sister, Mrs. C., was also insane. She was a chronic alcoholic showing a paranoid trend. She imagined that a certain clergyman was in love with her, that he annoyed her by making references to her in his sermons and by looking at her in a "loving" manner. She was also in love with him, but the spirits warned her to keep away from him. Investigation showed that she became insane about six years before Mrs. Love showed any symptoms. Mrs. Love was at first fully aware that her sister, Mrs. C., was insane; she consulted physicians and tried in every way to cure her sister, C. Later, however, she maintained that there was really nothing mentally wrong with her, that she drank too much occasionally, and explained her sister's delusions by saying that everything was perfectly comprehensible, that certain spirits communicated with both her and her sister C., and that she was trying very hard to overpower those evil spirits. Moreover, it was soon discovered that Mrs. Love became interested in spiritualism because her older sister, Mrs. C., talked of hearing "spirits," that in her repeated efforts to appease the annoyed divine, the object of Mrs. C.'s affections, she herself became enamored of him, but as she was rebuffed she gradually rationalized everything and formed the system mentioned. It is very significant that the name "Gandini," her medieval spirit lover, phonetically resembled the name of the clergyman annoyed by her sister. Without giving the other features of the case I will state that we dealt here with a case of *folie à deux*, or in terms of Freud, an identification between two sisters who were both burdened by heredity.†

*Read before the Vidonian Club, Oct. 31, 1919.

†The same unconscious identification can also be seen in hysteria and the psychoneuroses.

As we get away from the extremes we come to the more refined forms of identification as seen in fancies and normal identifications. Thus, I know a man who almost daily identified himself with someone who appealed to him. He was not aware of it until he was analyzed and he then discovered that hardly a day passed during which he did not "feel like someone" to whom he looked up in the past or present. He would assume certain mannerisms of this particular person, he would visit places, read books, and use expressions that were characteristic of the person with whom he unconsciously identified himself at that time. A similar mechanism of this kind is seen in the normal between teachers and pupils. Students very often imitate their favorite teachers and show it in many ways; here, too, it is not conscious imitation, it is usually quite unconscious. Perhaps the deepest form is the identification unconsciously shown by children. One can easily see how a child constantly strives to talk, to move, and in every way to identify himself with his parents; children openly state that they wish to be like father or mother, and this is naturally always encouraged by the parents. As the child grows older and emerges from his home microcosm he shows at first a very marked sensitiveness to persons and objects encountered in the outer world. He views everything with suspicion and fear and gradually has to become accustomed to the new world. The reason for his behavior is the fact that he seeks for the same process of identification everywhere, and as the outside world does not fall in with his familiar *milieu* the child becomes frightened and makes an attempt to run away from it. It is well known that almost all children are afraid of strangers, or being accustomed to white people they cry at the sight of a colored person. Children from rural communities usually fear the city, and foreigners, although no longer children, behave in a similar way. Instead of mixing with the natives they unconsciously gravitate to a neighborhood that resembles their former environments. Observe, for example, the different foreign colonies in a city like New York; it is from these colonies that sooner or later they emerge and are lost in the melting pot. It is thus clear that the easier one can identify himself with persons and situations the less he fears and suspects them and the better is his relationship to other people. A cosmopolitan is one who can find himself at home everywhere. The Jews, for example, who were for centuries driven from country to country can readily acclimate themselves anywhere.

The same phenomena are observed among animals. Mr. Stefánsson, in his fascinating work, "My Life with the Eskimo," describes how he dis-

covered an easy way of hunting the seal. The usual methods followed by the Eskimos were found impractical because the seal, who is very suspicious and observant, rarely ever leaving his hole in the ice, rapidly glides into it as soon as he observes any change or anything strange in his neighborhood; it is quite impossible to elude his vision even from long shooting distances. So watchful is the seal that every few seconds he wakes up from his deep slumber, turning his head all around the horizon to guard against any hostile approaching. Stefánsson soon noticed just how often, at what intervals, the seal went through these girations and then set out to beat him in a most ingenious manner. He started by imitating the seal's mode of locomotion; with a stop-watch and a gun he kept on sliding on his belly on the ice as long as the seal was slumbering, lying low when the seal made his observations, and now and then imitating the seal by raising his head and going through the same movements as the seal. In this way he made the seal believe that he was a seal and so could come within easy gunshot. Mr. Stefánsson maintained and proved that a white man could live well in the far north without dragging along a big food supply. But, as you see, it could only be done through an effort at identification or through descending to the level of the environments. "When in the Arctic region be a seal" seems to express a deep psychological fact of great utilitarian significance.

But what could this great thinker have meant by "When in Rome be a Roman," which I have just paraphrased? He undoubtedly wished to imply that in order to be happy one should always endeavor to be an integral part of the environment in which he happens to be. To be more explicit one should make every effort to feel or read himself into the *milieu* in which he lives, so that he will be thoroughly identified with it; and the more perfect the identification the better for the individual. For no animal will suspect or harm you if you can look, act, and smell like the animal. No one will suspect your loyalty if in America you will act, talk, and look like a true American. Through the word *barbaros* the ancient Greeks designated not only a foreigner but also one whose mode of reaction so differed from theirs that they felt justified in looking upon him with suspicion. That undoubtedly accounts for the modern meaning of the word "barbarian."

But judging from Mr. Stefánsson's behavior to the seal one could ask whether it would not be just as easy to say, "When you are in Rome make believe you are a Roman," and many observations from everyday life would seem to answer this affirmatively. Psychoanalytic investigation, however, shows conclusively that although this could be followed with the seal and with some bipeds who are endowed with seal attributes, it is actually impossible in reality. In other words, true identification is altogether an unconscious process; once it may have been conscious but it then became, as it were, a second habit. No normal person can identify himself for any length of time with a person or situation that is foreign to his own feelings; the true actor lives through his part, as it were.[3] Abnormal persons often make believe that they are feeling or reading themselves into a situation, but any trained observer easily sees through them. We all know how simple it is to detect the simulator or malingerer in psychiatric practice. As a matter of fact, one can state that every individual always follows definite forms of identification which are unconscious and into which he constantly strives to read himself. The transference mechanism upon which the Freudian school has thrown so much light depends altogether on identification, one might say it is only a finer form of it. As is known, in coming in contact with people one consciously and unconsciously tries to make a good impression. If done consciously it is usually a failure because the persons for whom it is intended readily feel that it is forced and artificial. A good transference is a matter of feeling, there is no need for a conscious effort, it is spontaneous, so to speak; one meets, one sees, and there is friendship. This mechanism is, of course, most important in our dealing with patients; unless the patient feels like a child in a familiar environment very little can be done for him. In fact the success or failure in the management of a mental patient depends altogether on the first meeting. This in no wise differs from our everyday relations with non-neurotics. As in the case of Charles Lamb's two men who never met before and who began to fight as soon as they glanced at each other, we would either manifest open friendship or hostility on first meeting—a mechanism which one readily sees among children and animals. As Shaler[4] puts it: "The matter is of such moment that it may be said again in brief that the way in which the neighbor meets us when we greet him is of exceeding importance. Every such meeting is a psychological crisis by which all the subsequent relations of the person are likely to be shaped." These words were written by a keen observer who undoubtedly never heard of Freud. In brief, when one deals intimately with all types of people as one is wont to do in psychoanalytic work, one soon realizes that unless the relations between himself and the patient are good, unless there is a friendship and mutual respect which begins at the first interview, one will have to overcome almost insurmountable difficulties later. That accounts for the many difficulties encountered in the mental treatment of Jews by non-Jews and in the treatment of Jews who no longer wish to be identified with Jews, by Jewish physicians. In the first case the non-Jewish physician has to be divested of his latent prejudices and in the second case the patient has to be helped to face reality by frankly admitting his origin.

From what has been said one can readily see how important it would be for both patient and physician if one were able to dominate the psychological difficulties of first encounters with neurotics and control the situation, as it were. For almost ten years I have asked most of my patients during our first interview the following question: "What personage from history or legend do you admire most, or whom would you consider your ideal?" I have collected answers to this question not only from patients but also from friends, acquaintances, from some college students, and from school children. In putting this question I assumed that the person we admire most, who is our ideal, expresses in his life our conscious and unconscious strivings. That

is to say, we admire this personage so much because we would wish to be like him and are always endeavoring to emulate his mode of reaction to the world. It will perhaps be surprising to hear that over 90 per cent. of my male answers confined themselves to only five historical persons. Of 586 male adults, 396 answered "Napoleon," 101 answered "Lincoln," 38 answered "Cæsar," 26 answered "Washington," 16 answered "Frederick the Great" and the rest, 9, had various other ideals. Perhaps the most significant part is that over 70 per cent. had Napoleon as their ideal and that of the 586 men only two answered "Jesus.' And considering that 80 of 586 gave Cæsar, Washington, and Frederick the Great as the persons whom they admired most, and that Lincoln who stood next to Napoleon among American born men although not a soldier was not a weakling in any sense, one can readily see what the average intelligent person's ideals are. He evidently admires most a man of action who can put in operation those impulses which he himself would wish to live through but dares not or cannot do so. This also demonstrates that we are not as ideal in our unconscious strivings as some make us believe, that the good book is correct in asserting "For the imagination of the human heart is evil from the beginning." Only two Christians out of over 60 per cent. of Christians took Jesus as their ideal. One was a physician who had given up the practice of medicine and lived on a ranch, and the other was a literary gentleman who lived on his income. These answers also explain why things primitive fascinate us, why plays dealing with crime are popular, and why most of the news items in our daily press are not exactly about the cardinal virtues in men.*

The term "empathic index" was coined by Prof. E. B. Titchener and deals with the idea of reading oneself into an inanimate or animate object. Dr. E. S. Southard[1] wrote an interesting paper on the subject but treats it from an entirely different angle. As I said above, the object of my question was to ascertain the ideal one is unconsciously endeavoring to emulate; it has nothing to do with reading oneself into an inanimate object. However, I feel that the expression "empathic index" aptly covers, as a generic term, the ideas involved in my question. I might say the answer to my question denotes the person's empathic index, and that the empathic index definitely shows the trend of the person's adjustment to the world. Examination then shows that one can speak of a racial empathic index as seen among Jews, of a national empathic index as seen in Americans, Frenchmen, or other nations and of a biologic empathic index. The last is common to all; it is essentially human in its manifestations. Among my test persons who answered Napoleon, there were men descended from many races and nationalities. Napoleon and Cæsar express the aggressive component common to all male animals, that is why they strongly appeal to us. It is the domination of this same component which explains why at the apex of the war when feeling against Germany was at its height (in the spring of 1918) eleven Yale seniors, when requested by their class statistician to tell who, in their opinion, now deserved to be called "the man of the hour" gave the name of the German Kaiser. The official who took this vote denied that these men were in any way pro-German.* Like all mechanisms based on feelings the empathic index is readily expressed by the lower classes and by children who have not yet reached maturity. A good illustration of it is found in nicknames. I am in the habit of asking my patients whether they ever had nicknames; I find that the nickname given by classmates or friends usually shows the person's empathic index. Thus most of my effeminate homosexuals long before they were conscious of it were nicknamed by their classmates: Mollie, Sarah, Jane, Nellie, etc.; others of the masochistic type were nicknamed: Kid, Shorty, Frog, Speed (meaning slow by contrast), John L. and similar names. That one can lend credence to the empathic index is illustrated in this example: As soon as the draft law was passed, a number of my former patients, some of whom I had not seen for years, came to me and admitted their fear lest they should be drafted into the army. I was interested in their empathic index and on looking up their histories I found that one gave as his ideal "Benjamin Franklin," one "Pestalozzi," and one "Florence Nightingale." I then looked up the histories of those former patients who volunteered their services and found that all showed a normal biologic empathic index.

The empathic index is usually influenced by age. Of the 101 test persons whose answer was "Lincoln" most were over the age of 38 years, and over 90 per cent. of them were married men. I might mention that "Lincoln" was also given as second choice by a great many whose first answer was Napoleon. I disregarded it because the first answer is always the correct one, the second is a product of reflection. Napoleon and Cæsar represent the absolute primitive while Lincoln represents a sublimation of it. The empathic index of children (kindergarten age) is very interesting. I asked a teacher to explain to the children the meaning of a hero and give them examples. A few days later every boy was asked who was the greatest hero and the answer was invariably "father."

School boys of Grammar School age showed an indefinite empathic index. They were asked to write a composition about the greatest personage they had read or heard of and give their reasons. Very few took their own fathers, most of them mentioned some general from the history book or a character from fiction, quite a number took their teacher as their ideal; that was particularly true of boys of foreign parentage.

It is difficult to obtain definite answers from insane patients. Manic patients invariably took some famous or notorious person. Paranoiacs are usually guided by their delusions. Thus a religious paranoiac took God as his ideal, another answered that the prophet Isaiah was his ideal. Some who could be induced to answer the question often thought a long time and said, "I am my own ideal

*My attention has been called to the fact that the wording of my question, "What personage," etc., precludes the answer "Jesus," as Christians consider Christ a deity and not a personage. There is little validity to this argument when one thinks of the second part of my question. "Whom do you consider your ideal?" which certainly does not exclude Christ, and the fact remains that two test persons thought of Jesus in answering my question.

—or, I have no ideal." Præcoxes usually refused to give any answer.[1]

I regret to say that I have not been able to tabulate and report the answers given by women. The remarkable thing about their answers is that very few women gave females as their ideals, they invariably mentioned male names. Lincoln and Washington seemed to stand highest. This clearly shows that the ideal of a woman is a man and recalls Nietsche's pithy remark: "A man says I will, a woman says he will." The woman's empathic index always shows the type of man that appeals to her.

The empathic index does not necessarily tell us anything that one may call altogether new; but it furnishes a new and quick method of observing the person's mode of adjustment; and one can truly say: "Tell me your empathic index and I will tell you who you are."

MODERN TREATMENT OF OBESITY.*

BY EDWARD C. TITUS, M.D.,
NEW YORK.

ABOUT eigtht years ago, while in France, I visited Professor Bergonie at Bordeaux in order to acquaint myself with his work in electrotherapeutics, of which I had learned through his contributions to the literature of this subject.

Among other procedures I became especially interested in his method of treating cases of obesity. For this purpose he made use of a modified Faradic apparatus which produces fibrillary and gross muscular contractions, both local and general. His results appeared so excellent that after my return I had an apparatus constructed on similar lines, but modified in some particulars.

During the past seven years I have employed the Bergonie method in such cases of obesity as could be kept under the necessary supervision, and my results have been so satisfactory that I have thought it worth while to bring it to your attention.

Prof. Bergonie read a paper before the Academy of Science in 1909, upon the employment of electricity in order to induce a general exercise or stimulation of the muscles of the body toward a therapeutic end. In this article he embodied the observations and results of his method over a period of nine or ten years.

*Read at the annual meeting of the American Electrotherapeutic Association, September, 1919.

The principle upon which the treatment is based can be summed up as follows: The proper use of any organ increases its vitality and also influences the development and function of the entire organism. The application of this principle is utilized in the development of the muscular system. Electrically provoked exercise consists of muscles being contracted in physiological rhythm, both in rate of muscle fibrillation (about 30 per second) and frequency of heart action.

To induce such exercise without fatigue is a desideratum which has long been sought, for combating those conditions in which combustion is insufficient, as presented in cases of obesity, some forms of diabetes, and all forms of suppressed uric acid elimination.

Of the various currents employed, the one finally selected and which is now giving the greatest satisfaction is derived from what may be called a coarse-wire Faradic, the aim being profound muscular contraction without pain or fatigue, physical or mental.

The current is rhythmically interrupted and reversed by a well-known mechanical principle, and timed to correspond with the heart action. The interrupter or vibrator is made to operate at 30 per second—the rate of normal muscle fibrillation. This together with the gross muscular contractions corresponding with the pulse frequency, and regulated during treatment to changing heart beat, seems to be an ideal means of inducing absorption of fat deposits and infiltrations, and of promoting the necessary elimination of products of tissue waste, plus better development of muscular structure. For it will be found that as the treatment progresses the decrease in size and change in contour will appear to be greater than the actual loss in weight would indicate, because the reduction in weight due to the absorption of adipose tissue is nearly equalized by the development of normal muscular structure. This, however, is but a part of the improvement or desired result.

Deep respiratory excursions are involuntarily induced and a greater activity of both skin and kidney function is likewise observed. Patients who seldom perspire will develop a most active diaphoresis and diuresis, and it is not uncommon to have them void from 12 to 16 ounces of urine, which is both physically and chemically normal, at the end of an hour's treatment. This increased elimination usually persists long after the treatments have been discontinued, even upwards of a month.

It must not, however, be inferred from these remarks that this method alone constitutes the whole treatment of obesity. This condition is of such complex and diverse origin that the treatment must be individualized in accordance with the causative factors, and the use of the Bergonie method must at times be supplemented by such other measures as may be indicated.

In accordance with Gutman I distinguish two general types of obesity—endogenous and exogenous.

Endogenous cases are characterized by a low oxidation quotient—low rate of metabolism, diminished oxygen consumption, and a low respiratory quotient, and their causes may be summed up as follows: (1) Disease of the pituitary. (2) Disturbances of the

thymus, thyroid, liver, or pancreas. (3) Disturbances of the sexual apparatus. (4) Menopause, pregnancy, and lactation.

The exogenous type, which is chiefly due to excesses of diet and lack of exercise, frequently merges into the endogenous, so that the treatment of the two may be discussed together.

Before beginning the treatment of any case of obesity it is necessary first of all to inquire into the history, which will frequently furnish valuable clues as to the cause, and follow this by a careful general examination with the view of determining the presence of other diseases with which the obesity may be associated. As is well known, obese subjects often present evidence of functional or organic diseases of the heart, arteriosclerosis, diabetes (some authorities claim that from 40 to 80 per cent. of all obese subjects show sugar in their urine and other evidences of this disease), enlargement and fatty infiltration of the liver as well as of the kidneys, and invariably marked intestinal autointoxication.

The presence of such associated conditions must be carefully considered in the treatment.

It will be seen, therefore, that I do not depend entirely upon the Bergonie method, but employ it as a most useful adjunct in all cases irrespective of the cause. Its universal use is based upon my observation that it excites all glandular activity as evidenced by increased secretion of urine and perspiration, improved digestion, and bowel function.

While its beneficial effects upon nutrition are shown by a gain in strength and general well-being, so that patients who have previously been languid and easily fatigued, are only too willing to follow directions as to walking, gymnastics, and other exercises, there is also a distinct improvement in circulation, heart action, and respiration.

In view of the fact that insufficiency of the endocrine system plays so important a part in the etiology of obesity, I have occasionally resorted to administration of various glandular extracts, single or combined, for a short period only, as indicated in the individual case. Thus I have often employed with benefit thyroid, pituitary, ovarian, pancreatic, mammary, and testicular extracts as well as the combined hormones.

On account of the general presence of intestinal autointoxication I have also frequently prescribed liberal doses of bicarbonate of soda and powdered rhubarb and one to three drams of finely granular agar-agar after meals.

As regards diet, the general principle has been gradually to reduce the quantity of food and eventually to eliminate all meats and most of the sugars and fats. But each case should be a law unto itself in the matter of dietary regulation.

As the Bergonie treatment is no doubt known to you all, I shall refrain from giving more than a description of its mode of application, especially mentioning the points which I have found of particular importance.

This treatment should never cause fatigue. Most patients can tolerate an initial application of one-half hour, and this can be increased ten minutes each day until up to one hour in duration. Prof. Bergonie has advocated that this full time can be borne by some patients twice daily, but I have found that one application per day is usually "a genteel sufficiency."

Since simultaneous stimulation of the entire musculature is to be obtained, the electrodes should be of ample size to cover the greatest area of the body surface.

These electrodes are of two kinds. The stationary are attached to the semi-reclining chair, much like the ordinary steamer variety, but larger and more stoutly built. Extending the full length of the back of the chair are two large metal electrodes, divided in the center, two on the seat for the buttocks and thighs and two on the adjustable extension for the legs. Attached to each of these electrodes is a cable connecting with the corresponding rheostat of the machine.

The movable electrodes are six in number—two for the arms, two for the abdomen, and two for the anterior surface of the thighs. They should be as large as possible and shaped to comfortably fit the contour of the parts.

The chair is covered with a moderately thick bibulous towel wet with warm water, and the movable electrodes are slipped in suitable sized covers (like a pillow slip) also wet. It is very necessary that the covering material of all electrodes should be of the same thickness, as the tension of the current from the machine to the patient being only 24 volts, the slightest difference in this detail will make the current irregular and quite unsatisfactory in its effects. The total area of surface covered by all the electrodes may amount to 10,000 cubic centimeters.

The arm electrodes can be held in place by a Crepe-Velpeau bandage because of its elastic quality; while those on the abdomen and thighs are best secured by canvas bags filled with gravel or coarse sand. The total combined weight of these bags may vary from 50 to 100 pounds. They exercise considerable pressure which becomes an advantage in keeping the electrodes in good contact, and giving the muscles more work to do when they contract. This great weight is readily moved by the contracting muscles without the least fatigue or painful sensation. Were it not for the electric stimulation of the muscles, the above-mentioned great weight would be both difficult and painful to support.

The subject removes all clothing but shoes and stockings. The body is covered with a suitable-sized sheet, the opening coming to the back and pinned together at the nape of the neck only. This is separated as the patient sits down in the chair, the naked back, etc., coming in contact with the moistened towel, while the sheet affords ample covering for the anterior surfaces.

The movable electrodes are adjusted next to the skin and the sandbags put on outside the body covering.

The machine should be tested in all its mechanism before each treatment to insure against unevenness of current and possible unnecessary shock. When this detail has been observed, it is my custom to begin the treatment by adjusting the current consecutively with the rheostats controlling the arm electrodes, the back, abdomen, buttocks and thighs, and lastly the legs.

The contractions should be only feeble at first, and

after ten minutes or so gradually increased to a comfortable tolerance and eventually to vigorous muscular contractions.

The usual course of treatment should extend over a period of from six to ten weeks. The applications should be daily for the first three or four weeks, then on alternate days for a similar duration. If further necessary, at longer intervals as the case may require.

It will be noted that improvement is evident from the beginning of treatment. There will be a decrease in the gross dimensions out of proportion to the loss of bodily weight. This can be accounted for by the development of muscular structures and the absorption of the bulky adipose tissue.

In some patients where rapid reduction and detoxication are urgently demanded I employ for the first three days, in addition to the Bergonie treatment, a diet of weak tea and lemon water, small quantities of dry toast and fresh crisp lettuce ad libitum, together with liberal doses of saline laxative water morning and night.

It is reasonable to expect—and this has been my experience—that in those cases where the patients conform to the requirements in regularity of treatment, diet, and indicated exercises, a reduction averaging from half to one pound or more per day will be secured.

It is pleasant to add that usually the improvement, as manifested by a sense of well-being, greater activity, and more attractive proportions, will continue long after the treatment is terminated.

127 West Eleventh Street.

ACTION OF ELECTRICAL CURRENTS ON DUCTLESS GLANDS AND OTHER TISSUES.*

By FREDERIC DeKRAFT, M.D.,
NEW YORK.

Until recently, but little attention has been paid to the possibility of stimulating the action of the glands of internal secretion by means of electrical currents. High frequency currents, applied in a general way, promote nutrition of the body as a whole. They check toxins; they aid in inducing chemical changes in the tissues, as is evidenced by the very great increase in solid constituents of the urine, by the increase in the excretion of CO_2, and by the increased activity of the sweat glands. The hair loses its brittleness and dryness, becoming soft and oily, regaining its natural luster; the skin loses its dryness and tendency to desquamate; the nutrition of the nails is improved, as shown by their rapid growth, greater firmness and improvement in color.

By the *local* application of diathermy we find we can influence the circulation of arterial blood in any glandular organ, thus increasing its activity and promoting its functional action. No organ is so deeply seated that it cannot be reached by the vivifying warmth of high frequency currents. This introduction of warmth into the tissues or organs produces a vitalizing effect; the activity and metabolism of the cell are increased, and its resistance to pathological processes is raised.

By means of large electrodes applied to the abdomen and back, or of the multiple electrode method (general diathermy) and large volumes of diathermic currents, we can raise the temperature of the blood. The longer the period during which diathermic currents thus applied are allowed to act, the more marked will be the effects, both immediate and remote. As the result of the heating of the entire blood stream, and of large masses of tissue, the capillaries of the skin and of the mucous membranes of the nose, throat, and bronchi become widely dilated, and much of the blood thus drawn to the surface for cooling is withdrawn from the splanchnic circle. Anemia of the splanchnic area ensues, and visceral congestion is removed. The liver, the intestines, and other organs are made to disgorge stagnant venous blood; the skin exudes sweat and sebum freely; there is marked increase in watery vapor from the skin and mucous membranes; the respiratory excursions are increased in rapidity and depth, improving the oxidation of the blood. All the organs within the abdominal cavity are placed in a state of better nutrition, and their activity increased, or, if impaired, restored. Their capacity to defend themselves against the invasion of toxins and bacterial colonies is augmented.

Coincidentally with the improved activity of the glands of internal secretion, the nutrition of the entire body improves. We commonly find an improvement in the ovarian activity and in the menstrual flow in the female; in the male, it is possible, both by the direct local method and by the more general method to increase testicular secretion and improve sexual vigor.

Each organ, each cell, every tissue of the body, though it may seem to be independent in action, exerts some influence on other tissues of the body. The ductless glands, or endocrine organs, produce hormones which are in some cases synergistic, in others antagonistic.

About the year 1849, Professor Berthold, of Göttingen, transplanted the testicles of young cocks into the tissues of pullets, and found that hens so treated developed the masculine voice, comb, sexual preference, and love of combat. About twenty years later, Brown-Séquard came to the conclusion that a gland, whether possessed of ducts or not, elaborated certain substances which were essential to the growth and maintenance of the body, and to the preservation of health and function. By experiments on himself he showed that the result of the injection of testicular juice was an astonishing revivification of the physical and mental powers.

The acid chyme, as it passes into the duodenum, stimulates the epithelial cells of the mucosa to the production of substances which call forth responses from the pancreas, liver, and intestines, and the secretion of pancreatic juice, bile, and intestinal juices results.

Digestive poisons impair metabolism, and may cause atrophy of the thyroid and genital organs. They also impair the nutrition of the skin, hair, and nails, which become dry and lifeless. They affect the eye, causing early and rapidly progressive presbyopia. These conditions may be easily remedied by the general and local application of high frequency currents, by the static modalities, and the application of the sinusoidal current to the abdomen and back. The action of intestinal poisons

*Read at the annual meeting of the American Electrotherapeutic Association, September, 1919.

upon the general nutrition of the body is undeniable. All cells, particularly blood cells, suffer from their influence. Thus we frequently see all the signs of early senility in those individuals who suffer from intestinal autotoxemia.

The peculiarly harmful effects of intestinal poisons on blood cells and on glandular structures such as the liver and pancreas, naturally act detrimentally on other endocrines structures, such as the thyroid, thymus, hypophysis, testes, ovaries, etc.

J. H. Pardee (*Arch. Inter. Med.*, Feb., 1919) speaks of certain patients who develop, periodically, an intense craving for sweets, a sort of dipsomania for sugar. The candy sprees are almost always followed by a typical pituitary headache. We know that the pituitary (with the adrenals) controls the mobilization of sugar in the body. Owing to the excessive drain on it, the pituitary gland becomes enlarged, and then the suprarenals are called upon to assist in mobilizing the sugar, resulting in their great fatigue, and the formation of a vicious circle.

Want of sufficient muscular exercise also taxes certain of the endocrine structures excessively, and is a causative factor in diabetes mellitus, obesity, and gout, inasmuch as the muscles of the body, particularly the large voluntary muscles, are the sugar storehouses of the physical economy.

Clinically and in the laboratory, surgery has played an important part in helping us to acquire a better comprehension of the disorders of the thyroid, thymus, and pituitary. In the case of the thyroid gland, surgical misjudgments have also made it clear that the symptomatology of hyperthyroidism and hypothyroidism may merge to a surprising degree. Thus, patients suffering from nervousness, tachycardia, and exophthalmos have been subjected to arterial ligation and partial thyroidectomy despite the presence of a dry puffy skin, subnormal temperature, and other signs of glandular insufficiency. A long continued glandular overactivity is frequently followed by glandular exhaustion.

The *x*-ray has frequently been of diagnostic importance in helping us to outline the configuration of the pituitary fossa and that of the thymus, and has also been extensively employed in goiter for the purpose of reducing the size of the gland. However, the mere shrinking of the goitrous mass has been found to be insufficient, symptoms usually continuing because the underlying condition has not been removed.

Olivier reports two extremely serious cases of exophthalmic goiter treated successfully by means of the galvanic current. (*Paris Médical*, Oct. 5, 1918.)

The first case was that of a woman of 26, who had suffered from the condition for three years, and in whom hematothyroidin had failed. Owing to the extreme weakness of the patient, section of the cervical sympathetic had been refused by the surgeon. Her weight was reduced to 81 pounds. The treatment was as follows: a broad electrode, attached to the negative pole, was placed over the neck, and a similar electrode, attached to the positive pole, was placed over the back. The current strength was gradually increased to sixty volts and eighty milliamperes. Duration of each treatment, 30 minutes. Five months ofter the beginning of the treatment, the patient's weight was 130 pounds, and her pulse rate had fallen from between 140 and 150 down to 80. Thirty-seven treatments were given, daily at first, later, at longer intervals.

The second patient was a woman of 48 years, with extreme tremor, a pulse rate of 180, a large soft goiter, diarrhea, vomiting, and marked emaciation. She was unable to walk. Forty-two treatments were given. After the eighth treatment, she could walk a considerable distance. When seen three years later, she was still in good health.

These cases recall to mind the method employed thirty-five years ago, namely, galvanization of the cervical sympathetic, which was successful in many cases. It seems certain that when a galvanic current is applied in the manner described by Olivier, not only is the goiter directly affected by the action of the current, but, still more important, the sympathetic and pneumogastric nerves share in the stimulation, and so does also, through them, the visceral nervous system. The thymus also comes under the action of the current.

In 1895, von Mikulicz called attention to the occurrence of enlarged thymus in severe cases of exophthalmic goiter. In 1908, Hart gave it as his opinion that abnormal activity of the thymus might produce the clinical picture of Graves' disease. The thyroid, thymus, and stomach seem to be in a measure interdependent.

About eight years ago, a young school teacher suffering from goiter came under the author's care. The skin of her face was yellow, almost as in jaundice, and dry. Her tongue was coated, she was constipated, weak, and nervous, and had not menstruated in six months. Exophthalmos was present, and her heartbeat was about 130. General diathermy was employed twice weekly to the point of profuse perspiration, followed each time by the application of the glass vacuum electrode attached to the Oudin of a transformer. In this way a hot, strong current was applied for about one to two minutes' time. At each treatment there was a distinctly visible contraction of the goiter.

After eight such treatments the menstruation appeared, the pulse rate subsided, the skin lost its yellow tinge, and the patient apparently recovered. She has had no subsequent attack.

The diathermic current may be still more successful in these cases when applied to the neck and back. In cases of hypersecretion, a heavy current should be used for the purpose of inhibition, but where there are evidences of hyposecretion a mild diathermic current continued for an hour, tends to stimulate secretion.

When treating cases of glycosuria with diathermic currents, it must be borne in mind that hyperthyroidism may inhibit the action of the pancreas.

Dr. Titus has described to you the detoxicating influence of a suitable diet, and of muscular exercise, both voluntary and, in proper cases, provoked by means of a coarse faradic current applied to the principal muscles of the body.

In suitable cases, a considerable success may be obtained by employing the resonator effluve from a large static machine. An inducto resonator is used and the bipolar method is employed. A metal plate attached to the Tesla is placed over the abdomen, and the effluve from the Oudin applied gradually over every part of the back; the plate is then applied to the back, and the effluve electrode is gradually moved all over the body and limbs in front. Rhythmic muscular contractions of large muscle masses are produced; active tissue change results; the specific gravity of the urine becomes

higher, and there is a marked increase in the output of urea.

This treatment materially increases the muscle juices. There is an improved muscular tone, a general sense of well-being, and a reduction of fat. In several cases this reduction has amounted to as much as 50 lbs. in sixty treatments.

In cases of obesity where the peripheral circulation is impaired, heart action feeble, considerable flatus in the intestines, and a low output of urea, the use of the static wave current over the abdomen has produced the following results: the heart action has become stronger, the digestion has improved greatly, the extremities, previously very cold, have become permanently warm, and the low urea output has been raised to normal. In one case, there was a reduction of 100 lbs. in weight.

The wave current, when applied with a large electrode over the abdomon, reduces the venous engorgement in the liver and other organs of the abdomen. This current of high potential and low amperage diffuses itself along the saline fluids of the body, and when the spark jumps across the gap at the sliding rods emerges at the point where it entered. Then follows an anodal opening contraction. When the current again enters, an anodal closing contraction is produced underneath the metal plate on the abdomen. In this way distinct contractions of both voluntary and involuntary muscular fibers are produced. In addition a general molecular bombardment of millions upon millions of cells throughout the body occurs from the surging character of the current. This results in increased combustion processes, and accounts for the relief afforded, and for the loss in weight.

In a considerable number of cases of mental disorder the patients have voluntarily stated that, as a result of the wave current applied to the spine and abdomen the head felt better, ideas came more freely, sleep was better, and there was a general sense of well-being. Among female patients of this class, many suffer from amorrhea: in these, menstruation returned. The hair, frequently brittle, dry, and falling out, improves in growth and texture; digestion improves, and there appears to be a stimulation of all organic functions.

The combined galvanofaradic-sinusoidal current serves a useful purpose in diabetes, gout, nervous and mental disorders, and in the various conditions associated with obesity. This current, applied with a pair of large electrodes, 10 by 14 inches, to abdomen and back, exercises the muscles of the erector spinal mass, the serrati magni, the abdominal muscles, and, to some extent, the muscles of the thighs and shoulders. As a result, the tension and strength of these muscles becomes greater, the posture of the body becomes more erect, with a consequent improvement in the depth and regularity of diaphragmatic action, which in turn stimulates the return of venous blood from the portal circulation as well as from the general systematic veins.

The improvement in the tonicity, volume, and strength of the abdominal muscles increases the intraabdominal pressure, tends to support the abdominal viscera, and brings about a more normal distribution of the venous and arterial blood in the splanchnic area, and the danger of displacement of the abdominal organs as a result of the disappearance of the supporting fat without improvement in muscular tone (a not inconsiderable danger where a rapid reduction of weight in a very obese person is attempted by diet alone) is avoided.

148 West Seventieth Street.

THE DIAGNOSIS OF ABDOMINAL TUMORS.*

By ALEXIUS McGLANNAN, M.D.,
BALTIMORE, MD.

NOWHERE in medicine is the advance of surgical technique over the progress of diagnosis more evident than in the case of abdominal tumors. The relative simplicity of an aseptic exploration of the abdomen, and the fact that most of the tumors require operation has intensified our interest in the surgical proceedure rather than in the diagnostic investigation.

With our best efforts diagnosis will remain doubtful in many instances and we are forced to operate on a tentative or a compromise decision. Furthermore, we have learned the lesson, that in some cases, especially in those of malignant tumor, to postpone the operation until a definite diagnosis can be made is to rob the patient of his opportunity for cure. However, by a careful study of these swellings we can often recognize their exact nature and be better prepared for their treatment.

In addition to ordinary physical examination, the diagnosis of an abdominal tumor may require the assistance of all the methods of investigation at our command, namely, clinical laboratory tests, *x*-ray examination, either with the contrast meal or after oxygen inflation of the peritoneal cavity, the special skill and knowledge of the gynecologist and of the urologist. When these means are employed in a proper manner the number of cases coming to operation without a diagnosis becomes relatively small.

In studying an abdominal swelling we must first decide that a tumor actually exists, then whether it is situated in the abdominal wall or within the peritoneal cavity. Should it prove one within the cavity, its origin and relations are problems to solve.

Sham and phantom tumors are frequent in the abdomen. These sham or false tumors may be contracted muscles, a portion of a normal organ, or a fecal mass. The commonest, probably, is the palpable aorta of thin and nervous patients, mistaken for an aneurysm by the inexperienced. With a true abdominal aneurysm various factors may make it impossible to distinguish between a heaving impulse and distensile pulsation, but in the absence of the latter sign we are not justfied in making the diagnosis of aneurysm.

Contraction of the upper part of the rectus muscle may resemble a tumor. This is more likely to be true in cases of pyloric ulcer, or irritation, when palpation of this region throws the right rectus into protective spasm, while the left muscle remains relaxed. In such a case the recumbent patient should be directed to sit up without using his arms. The even contraction of both recti will prove the muscular origin of the tumor.

*Read before the Ohio Valley Medical Association at its twentieth annual meeting at Evansville, Ind., on November 11 and 12, 1919.

In certain forms of ptosis the pylorus become palpable in the upper right quadrant, as either a finger-like cord or a nodule. Frequent and rapid changes in the consistence of the mass way be felt as the pylorus contracts and relaxes under the palpating fingers.

With emaciated patients the head of the pancreas may be felt in front of the vertebral column.

Fecal accumulations usually occur as tumors in the course of the colon. They are commonest in the cecal and sigmoid regions. When pressure of the finger on the tumor leaves a dent in the putty-like mass, the sign is pathognomonic. Some of the fecal masses become very hard from dehydration, especially those occurring in the colon in Hirschsprung's disease and behind obstipating tumors. Enemas before examination and the *x*-ray examination of the intestine will be found necessary in the study of such cases.

The tumor of intussusception is recognized by its cylindrical shape and by its situation close to the spinal column. The associated symptoms of acute intestinal obstruction are usually so urgent that this variety of false tumor is not likely to be confused with anything else.

Inflammatory masses are easily mistaken for tumors. The stump of a resected omentum may form a painful tumor, should it become infected or necrosed. Circumscribed areas of suppuration, especially those occurring in the region of the appendix, may form firm, immovable masses easily mistaken for malignant tumors. These masses evidently represent an unusual reaction on the part of the tissues to the invading organism, comparable to that occurring in the case of woody phlegmon of the neck.

The nodular and encysted forms of tuberculous peritonitis give rise to false tumors in the abdomen, most often in young patients. The diagnosis of tuberculosis rests on evening fever, the local slight but persistent tenderness, and the fixation of the tumor, which may be either cystic or solid. Attacks of partial or complete intestinal obstruction are frequent in the course of tuberculous peritonitis.

Phantom tumors are produced by a localized contraction of the abdominal muscles or by gaseous distention of some portion of the gastrointestinal tract. Such tumors are found in hysterical patients or malingerers. The swelling may be made to disappear by deep and rapid respiratory movements and always vanishes under complete anesthesia.

Tumors of the abdominal wall may be separated as follows: (1) Those in which contracture of the abdominal muscles produces no change in the relation of the tumor. These are tumors of the skin or subcutaneous tissue. (2) Those in which the contracture immobilizes the tumor. These are tumors of the muscles or fasciæ. (3) Those in which the tumor disappears when the muscles contract; these are under the muscles, almost always within the cavity—Nélaton's tumors.*

*Nélaton's tumors are fibromata or sarcomata situated between the peritoneum and the muscles of the abdominal wall. They disappear when the muscles contract, but may be distinguished from intraabdominal growths by the direction of their movement with respiration. Nélaton's tumors move with the abdominal wall, from before backward. Intraabdominal tumors move with the diaphragm, from above downward.

In examining swellings of the abdominal wall, epigastric and other forms of hernia must be kept in mind.

Having decided that the swelling is an intraabdominal one, the first fact to determine is the point of attachment of the tumor. When the mass is a fixed one this is usually easily decided. With a freely movable tumor, in the absence of a palpable pedicle there is likely to be some difficulty. This may be surmounted by using the circle of Pagenstecker. The mass is moved through its entire range, marking its position at intervals on the abdominal wall. When these marks are connected we shall have outlined the segment of a circle, the center of which will be at the point of fixation of the tumor. The concavity will be in the direction of the origin of the tumor.

This maneuver will, of course, be misleading in the case of parasitic tumors, which have made new attachments at a distance from their true point of origin, and in tumors growing from organs which are congenitally misplaced. Should the tumor have a wide range of motion in several directions, the curve will not indicate its attachment, but such a range points to a tumor of the small intestine, the mesentery or the omentum.

The diagnosis of tumors so large as to occupy almost the entire abdominal cavity is often difficult. The notched leucemic spleen and the nodular fibromyoma of the uterus form hard tumors of great size. Tumors of the kidney and of its fatty capsule are soft. The enormous peritoneal fibrolipomas may be confused with ascites or ovarian cyst. Ovarian cyst and hydronephrosis both form large smooth swellings. The upper border of the ovarian cyst is best defined, while the lower border is most distinct in the case of hydronephrosis. Gynecological and urological examination will distinguish between the confusing swellings.

A pregnant uterus should always be remembered as a possible explanation of the presence of a large tumor in the abdomen, and we must not overlook a distended bladder as another cause of a large cystic swelling.

With the point of fixation of the tumor determined, we next classify and distinguish between the various swellings originating in that particular locality. For the purpose of classification it is well to divide the abdomen into four quadrants and to take a segment from the inner angle of each quadrant to form a central umbilical zone.

In the upper right quadrant, therefore, the liver and gall-bladder, the pylorus and part of the body of the stomach, the pancreas, hepatic colon, the kidney and adrenal may be the source of a tumor.

Enlargements of the liver may be smooth or nodular. The smooth enlargements are those of obstructive cholangitis, of hypertrophic cirrhosis, and of abscess. The nodular swellings are those of lues, of cancer, and of the congenital cystic liver.

A round and soft tumor suggests an angioma or cyst, while multiple soft nodules suggest benign adenoma.

Both lues and cancer early in their course may form a smooth swelling of the liver. The Wassermann test should be made in all cases of enlarged liver and when it is positive, active antiluetic treatment should be instituted. Syphilis of the liver is

influenced very rapidly by active treatment. The congenital cystic liver is associated with congenital cystic kidneys.

The relation of liver swellings to the occurrence of ascites and of jaundice is of value in their differentiation. Obstructive cirrhosis, hypertrophic cirrhosis, adenoma, and cancer produce jaundice. Cancer is the only one of these which produces ascites. The association of tumor, ascites, and jaundice, therefore, makes a diagnosis of cancer of the liver. Abscess of the liver is usually recognized by the fever and other signs of infection. There may be jaundice, but no ascites develops. The previous history of one of the illnesses likely to be followed by liver abscess is of greatest importance.

The enlargement of the spleen in biliary cirrhosis and in Banti's disease will aid in recognizing these types of enlargement of the liver.

Echinococcus infection is rare in this country and cysts of this origin can be suspected only when the patient is one who has migrated from Bulgaria or some similar region.

Enlargements of the gallbladder may be so great as to make a tumor in the neighborhood of the umbilicus, or in the ileocecal region. Unless there are adhesions, such a gallbladder makes a movable tumor whose fixed point may be demonstrated by using Pagenstecker's circle. Such a swelling is a hydrops of the gallbladder and is produced by obstruction of the cystic duct. A similar tumor, less freely movable but tender, with constitutional symptoms of infection, will be an empyema of the gallbladder. Gallbladder swellings with jaundice indicate obstruction of the bile ducts. Painless enlargements with jaundice indicate new growth, while attacks of colic are associated with stones. A distended gallbladder with jaundice indicates pressure on the common duct, usually cancer of the pancreas. (Courvoisier's law). Carcinoma of the gallbladder produces a nodular tumor with jaundice, but without colic. Ascites is common in the course of cancer, rare in calculus obstruction. Cancer metastasizes to the supraclavicular glands.

Tumors of the pylorus are either indurated ulcers or cancers. The mobility of the tumor depends on the character of adhesions. Their gastric origin can usually be proven by the *x*-ray examination, as well as by study of the stomach contents after a test meal. Obstruction of the pylorus occurs in both varieties. Sudden onset of symptoms is usual in cancer, while a long history of dyspepsia is common in the case of ulcer.

A hard tumor deep in the epigastrium near the vertebral column is likely to be a swelling of the head of the pancreas. Whether this be due to chronic inflammation, to lues, or to cancer must be decided by the associated symptoms. The pancreatic nature of the disease is shown by disturbance of the intestinal digestion, best studied by estimating the diastatic activity of the feces (T. R. Brown. *Johns Hopkins Hospital Bulletin*, July, 1914, xxv, 200.) Hemorrhagic or milky ascites is suggestive of cancer of the pancreas. Metastases to Douglas' cul-de-sac may be misleading in women. True or false cysts of the pancreas form smooth round swellings in the middle line or to the left of it, between the tip of the sternum and the umbilicus. The tumor is seldom movable to any great degree. The protrusion most often is between the stomach and colon.

Tumors of the hepatic flexure are almost always carcinoma, and are recognized by alterations in the motility of the intestine and the loss of flexibility of its wall as shown by the *x*-ray examination. Tuberculosis and lues will resemble cancer in many ways.

Tumors of the kidney growing from behind the peritoneum cause bulging of the loin rather than in the abdomen. On bimanual palpation they are felt most distinctly from behind at the costo-vertebral angle of the last rib. The colon is pushed forward as the tumor enlarges. The final recognition of the nature of the tumor is made by the complete study of the urinary tract by modern urological methods.

On the left side the splenic enlargements and those of the kidney and colon must be considered.

With a spleen in its normal location, the enlargements of the organ can be made out as tumors coming from beneath the ribs, and moving with respiration. When the notches can be felt the splenic origin of the mass is quite certain. The protrusion is into the abdomen, not into the loin; and the colon is first pushed downward and then lies behind the swelling. The changes in the blood picture will identify certain types of enlarged spleen. The association of enlarged spleen with anemia and later with hepatic cirrhosis is characteristic of Banti's disease. The constitutional symptoms and the local signs of suppuration with a large spleen indicate a splenic abscess. Malignant tumors produce a general splenic enlargement with ascites and cachexia. A wandering spleen may be confused with some other pedunculated tumor, unless a notch can be felt.

Tumors of the transverse and splenic colon have the same characteristics as those described in the case of the hepatic flexure.

The tumors of the lower right quadrant are carcinoma of the cecum and appendix, tuberculosis, actinomycosis, or syphilis of the cecum, and encapsulated areas of chronic suppuration in the region of the appendix and cecum. A parasitic myoma of the uterus may become attached, and occasionally an ovarian cyst may be found in this region. Adenomyoma of the round ligament may form a tumor in either iliac fossa. The tumors and inflammations of the cecum are identified by the *x*-ray examination; the growths of the uterus and its appendages by a pelvic examination and by the menstrual history.

On the left side, tumors of the lower quadrant are those of the sigmoid, colon, and the pelvic organs. Giant sigmoid makes a sausage-like tumor which may fill up most of the lower abdomen. Carcinoma of the sigmoid is seldom palpable. Diverticulitis may result in an inflammatory false tumor attached to the sigmoid. A history of interference with the motor function of the bowel and the *x*-ray study enable us to recognize these conditions.

In the central umbilical zone we find the tumors of the small intestine, mesentery, omentum, of the umbilicus and its attached fetal remnants.

Tumors of the small intestine are usually hard and uneven, and associated with symptoms of intestinal obstruction of varying degrees. Sarcoma, submucous lipoma, pedunculated adenoma, and sim-

ilar growths which encroach on the lumen of the intestine are likely to be the cause of intussusception occurring in an adult.

Tumors of the mesentery are extremely movable and generally globular in outline. They are usually cysts, and most often occur in young girls. Aneurysm of the superior mesenteric artery forms a movable rounded tumor, which has expansile pulsation.

Omental tumors are either lipoma, sarcoma, or metastatic carcinoma. They are not as movable as the mesenteric tumors. The inflammatory sham tumor of the omentum has been mentioned. The sarcoma forms a hard, cake-like, irregular mass.

Meckel's diverticulum may form a cystic tumor of large size attached to the small intestine and with it freely movable in the peritoneal cavity; or it may also be attached to the abdominal wall, in which event the tumor will be fixed just behind the umbilicus.

Cysts of the urachus are found in the middle line, between the umbilicus and the position of the bladder. As both the diverticulum and the patent urachus are remnants of the fetal umbilical structure, some abnormality of the external umbilical scar is usually present with these tumors.

Retroperitoneal tumors in their growth displace the abdominal viscera. Some portion of the colon is usually stretched over the mass, if it be of any considerable size; and because of this fact, there is likely to be resonance in front of the tumor. Pressure symptoms, depending on the structures involved, are associated with the growth of the tumor. The tumor is situated deep in the abdomen, may be smooth or nodular, is seldom tender, but usually causes pain. Most often the tumor is a sarcoma.

RADIUM TREATMENT OF UTERINE HEMORRHAGE.*

By THOMAS C. KENNEDY, M.D.
AND
W. H. KENNEDY, M.D.
INDIANAPOLIS, IND.

A DISCUSSION of the pathology of uterine hemorrhage is deemed unnecessary at this time. Every physician in this audience has had many of these cases to deal with, and in every case has wished for a specific to control this, at times, dangerous condition.

Radium therapy has been almost entirely devoted to malignant conditions, but it is now being used more and more in the treatment of nonmalignant diseases. In order to understand the essential points of radium therapy it is necessary to have a knowledge of the physics of radioactivity.

The energy given off by radium consists of a radiation, and the liberation of a gas, called the emanation, which is said to be radioactive.

The definition of radioactivity, as given by the Standard Dictionary, is "the dynamic property found in certain bodies of high atomic weight, of spontaneously emitting peculiar and characteristic rays invisible to the eye and capable of penetrating objects opaque to ordinary light."

The radiation is made up of three distinct rays, alpha, beta, and gamma rays. In the treatment of disease with radium this classification is important, as the results of treatment depend largely on the class of rays used. About 90 per cent. of the total radiation is made up of alpha rays. They have but slight penetrating power, and are positively charged.

These rays are seldom used in therapeutics, and never in the subject under discussion. They have slight penetrating power and are the irritating rays which are likely to produce burns. However, these rays are very easily eliminated, a thin sheet of metal or even a few thicknesses of paper being sufficient to stop them. These rays are given off with a velocity of 2,000 miles a second. One mg. of radium gives off 13,600,000 alpha particles a second. Notwithstanding this fact, radium is said to lose only one-half its strength in 1,700 years.

Beta rays are made up of particles negatively charged and travel with a velocity equal to light. These particles are only about 1-1000 the size of that of the hydrogen atom. Beta rays form about 9 per cent. of the total radiation, but are not at all homogeneous, varying greatly in their power of penetration. Some are little more penetrating than the alpha rays and are known as the soft beta rays; others, called hard beta rays, are exceedingly small and have great speed and power of penetration. Between these extremes are what are called the medium beta rays, which range from the soft to the hard beta rays.

The gamma rays form only 1 per cent. of the total radiation, but have great power of penetration. The gamma rays from 30 mgs. of radium can be observed by an electroscope after passing through a foot of iron. They have a velocity equal to that of light, and are a pulsation of the ether, in this respect being similar to Roentgen rays, but they differ from the latter in their greater power of penetration. M. Sagnac discovered that the gamma ray on encountering matter produces a secondary ray, similar to the beta ray. These rays have been called rayons de Sagnac by the French.

According to Rutherford 2 mm. of lead is sufficient to absorb nearly all the beta rays. On account of the difference in the penetrating power possessed by the different rays it is necessary to use screens of suitable material to eliminate the rays we do not desire to use in any given case. It is only very rarely that it is found desirable to use the alpha rays, as they are not sufficiently penetrating and readily produce burns. When they are used it must be for a very short time only. Metal screens have the double object of lessening the total amount of radiation and at the same time modifying the quality by filtration.

In the treatment of uterine hemorrhage the gamma rays only are used. The alpha rays and also the beta rays are eliminated by a metal filter or screen, which may be of brass, silver, gold, platinum, or other metals.

The cases of uterine hemorrhage coming to the Radium Laboratory for treatment may be broadly divided into two classes.

1. Cases in which there cannot be found a gross pathological condition. They come with a diagnosis of hypertrophy or hyperplasia of the endometrium, metritis, or endometritis. They have hemorrhage at puberty, at the menopause, or possibly throughout the child-bearing period.

*Read before the 20th annual meeting of the Ohio Valley Medical Association at Evansville, Ind., Nov. 11 and 12, 1919.

The treatment of these cases is frequently a source of great annoyance to the surgeon. After the use of all kinds of intrauterine applications and the administration of glandular medication perhaps, a curettage is advised. This sometimes overcomes the evil, but frequently the patient returns with the same old story. In not a few cases the surgeon finally in desperation resorts to a hysterectomy. But it is only after repeated failures that a conservative surgeon will advise such a mutilating operation. Among the most brilliant results obtained from the use of radium is in this group of cases. Indeed, very few cases of hemorrhage from the grossly normal uterus fail of permanent cure with radium.

2. Cases presenting a distinct gross pathological condition such as fibroid and carcinoma. In this class the bleeding cannot be considered by itself but must be taken up with the entire question of treating the pathological condition.

Occasionally a case of fibroid so exsanguinated as to make operative treatment inadvisable has been referred to us for radium treatment, with the intention of resorting to operation after the bleeding was checked and the patient became stronger. Two such cases have been so treated, and by the time the patient had regained sufficient strength to undergo an operation there was such a retrogression of the tumor that they both refused operation and at this time have no evidence of the tumor.

Technique.—The patient is given the routine hospital preparation for a vaginal operation. Gas is given and the cervix is dilated. The radium is in an hermetically sealed glass tube, and this is placed in a silver tube .5 mm. in thickness; this in turn is put in a rubber tube 5 mm. thick. The radium prepared in this way is introduced into the uterus and allowed to remain for from 12 to 24 hours. At the end of this period the radium is removed, the patient is permitted to return home with instructions to keep off her feet for a few days and to report her condition at the end of six weeks. As a rule we do not repeat the treatment under three months, but in our experience only a very few cases have required a second treatment.

Patients during the child-bearing period are given a smaller dose, as it is desirable to preserve the menstrual function. Patients at or beyond the menopause are given an application of from 600 to 900 radium hours, and this will usually be sufficient to produce a permanent menopause. In the greater number of our cases there has been at least one menstrual period after the administration of radium. It is well known that the effect of radium is manifested slowly. Some of the patients are treated shortly before the time for their period and consequently there is another menstrual flow before amenorrhea is produced.

Two cases only will be reported and very briefly.

Case I.—A girl of 17 suffered a severe metrorrhagia for three years, that is ever since she began menstruating. She had been given ovarian and thyroid extract and also uterine applications of various remedies. She was curetted and somewhat benefited for a few months. After about one year she began bleeding profusely again, and was curetted a second time. This not checking the hemorrhage, a hysterectomy was advised. The mother not being willing to have the operation, brought her for radium treatment.

The cervix was dilated and 50 mgs. of radium applied and allowed to remain 24 hours, which gave a total of 1,200 radium hours. She had her period in about three weeks but there was a cessation of the metrorrhagia. Since that time there has been complete suppression of the menstrual function with accompanying nervousness and hot flashes. I have been told within the last few months that she has been having a slight return of her menstruation and is in good health. I am not sure of this as the report came to me indirectly.

It is certainly not desirable to produce a permanent menopause in a girl of this age, but the end results are better than in an hysterectomy. We have learned that it is far better to give these cases a fewer number of radium hours, even at the risk of having to make another application. Now we usually give these young girls about 400 to 600 hours, which results in a temporary cessation of menstruation for a few months, after which there will be the normal menstruation. From the experience with radium in this group of cases in the last year we feel sure that the technique will be so improved and standardized that we shall be able to control the hemorrhage without producing a permanent menopause, which is so undesirable.

Case II.—Mrs. M., age 48. She gives a history of having a profuse menorrhagia for more than ten years. Frequently she became so exsanguinated that she was confined to her bed for several days at a time. For the last six months she had been totally incapacitated. She was curetted and her periods became regular and stayed so for about six months, when she had another severe hemorrhage. An hysterectomy seemed to be inevitable and as a last resort she was sent for radium treatment.

She was given 50 mgs. for 12 hours. The hemorrhage was checked for 8 months. It then returned and, while not profuse, was persistent. Another application was given and as the hemorrhage was not severe we gave her the same dosage as she had the first time, 50 mgs. for 12 hours. In about six weeks she had a slight show of blood but since then there has been a permanent menopause.

Radium will not be an ideal treatment until we are able so to regulate the dosage that we can check the hemorrhage and not stop menstruation permanently.

It is beyond the scope of this paper to discuss the second group, those cases presenting a gross pathological condition, as hemorrhage is then only a symptom. It would be necessary to take up the treatment of the gross lesion, for which I have not the time.

In regard to the carcinomas of the uterus we have found radium very effective in stopping not only the hemorrhage, but the foul discharge as well. Three years ago it was my privilege to report to this Association three cases of carcinoma of the uterus treated with radium. I want to take this opportunity to make another very brief report of these cases.

Case III.—Mrs. C., age 43. Referred to me by Dr. Ed. Clark; no cancer or tuberculosis in the family. In March, 1915, she had pain and soreness through the abdomen and back; had irregular menstruation and for some time the flow had been almost continuous. Her bowels had been constipated for years. She had had a great deal of pain all summer. On Sept. 7, 1916, she was curetted and cauterized, an hysterectomy being deemed inadvisable. She left the hospital on the 13th day. She continued to have pain and the hemorrhage and the offensive odor reappeared in a very short time.

I saw her on Oct. 13 at which time she weighed 93½ lb.; had marked cachexia, and was very weak and frail.

On Oct. 15, 1916, I gave her an application of 50 mgs. for 12 hours. The next day she felt weak, was

slightly nauseated, and had general malaise. On account of this condition I thought best to wait 48 hours from the time of the first treatment. On Oct. 18 I gave her the same treatment.

On the evening of the 18th, about one hour before I made the second application, she took morphine gr. ¼ for the relief of pain. Although she had been compelled to resort to morphine for the pain, she has never since had to take another dose.

I gave her altogether about 3,000 radium hours. The hemorrhage was promptly checked, as was also the offensive discharge. On Nov. 16 she weighed 96½ lb. and on Nov. 30 she weighed 105½, a gain of 9½ lb. in two weeks. About the 1st of January, 1917, she returned to her work as a millinery saleslady in one of our big department stores and has never lost a day on account of sickness in almost three years. There is no evidence of the disease on vaginal examination and she is clinically cured.

CASE IV.—Remained in good health for about 9 months when she succumbed to a general carcinomatosis.

CASE V.—Greatly improved and was able to get about although she had been confined to her bed for some time when she was treated. She lived about 7 months.

These three cases reported in 1916 were inoperable and hopeless. One is living, now three years, and in good health, and the other two received great benefit.

In the treatment of excessive hemorrhage from small fibroids radium is the ideal treatment. It will not only stop the hemorrhage but will produce a retrogression of the tumor. Clark, Kelly, and others have made reports on the treatment of uterine fibroids with radium with which you are all probably familiar.

Radium has not displaced surgery in the treatment of fibroids but in selected cases it has proven of great value.

In the treatment of uterine carcinoma it is invaluable. In all forms of uterine hemorrhage radium has proved to be a valuable agent, and as the technique becomes standardized it will be more effective.

THE INHALATION TREATMENT IN PULMONARY TUBERCULOSIS.

BY BEVERLEY ROBINSON, M.D.,
NEW YORK.

I AM prompted to write briefly on this subject by an article which appeared in the May issue of *Western Medical Times*. According to that article, Dr. Albert C. Geyser of New York, apparently does not think favorably of this treatment. It seems to him that what might appear to be due to treatment in a beneficial way is probably brought about by healthful conditions of food, air, and employment. Now, while all these latter may be most advantageous in promoting and establishing a cure when that is possible, or great amelioration of a patient's symptoms even when inhalations are not employed, I, for one, hold that dry vapor inhalations from certain volatile substances are very valuable and assist many times, in a sure and remarkable manner, when merely hygienic rules of life are not in themselves sufficient.

For many years in all cases of pulmonary tuberculosis, I have used and insisted upon the frequent, almost constant employment of the perforated zinc inhaler. With it, I am very apt to employ equal parts of beechwood creosote, spirit of chloroform, and alcohol. Of this mixture a sufficient number of drops, ten to twenty, are poured upon the moistened sponge of the inhaler and the inhaler is worn over the nose and mouth, while the patient inhales naturally, and without effort, the vapors which proceed from the mixture. The inhaler is held in place by two light rubber cords which take hold behind the ears. At first, the inhalation may increase the cough, and the patient finds it objectionable on this account. But this drawback is soon overcome by removal of the inhaler, after a few moments' inhalation and resuming its use after a short time of rest—say fifteen to thirty minutes. Very soon the patient can wear the inhaler without discomfort and, indeed, with some relief to cough and breathing, an hour or more at a time.

Before long, the patient can wear it almost constantly and with little or no discomfort. In many instances, one may sleep with the inhaler on during the entire night. The drops on the sponge should be renewed from time to time and whenever the odor of creosote becomes less appreciable. When the inhaler is worn almost constantly, it is well to examine the urine every day or two, and if a trace or more of albumin appears, to lesson the length of time or frequency of its use.

There are indeed, a few patients who cannot wear the inhaler for any length of time, or find it very irksome to do so. To these especially, I give a treatment of creosote in an acceptable form and in small or moderate and frequently repeated doses. A formula I have frequently and widely used in the past, is six minims of beechwood creosote, one ounce of the best glycerin, and two ounces of good whiskey. Of this I gave a dessertspoonful every two, or three hours. Even when the patient uses the inhaler frequently and almost constantly, I think it is wise sometimes to give creosote internally, in small doses.

Of course, if creosote is given internally by the mouth and also, used almost continuously with the inhaler, the frequent, almost daily examination of the urine must not be neglected. I am convinced that creosote should not be given undissolved in capsules, as they are often upsetting to the stomach. I am also convinced that creosote should not usually be given in anything but small, repeated doses, for a like reason, and besides, I do not consider it curative in large doses. Some patients, or their attendants, or indeed their near relatives, complain much of the very unpleasant smell of creosote. When this is the case I combine creosote with oleum pini sylvestris, or with compound tincture of benzoin, both of which have a pleasant odor and are also beneficial.

When the cough is very racking and evidently hurtful to the patient, pure chloroform may take the place, for a while, of spirit of chloroform, but when this change is made, the inhalation should not be prolonged at any one time and the effect of it should be closely watched and intermitted for a while, if in any doubt as to its helpful effects. There is much evidence to show that the use of pure chloroform in the inhaling mixture, will at times afford great temporary relief to cough.

Now then, a few words as to the effects from dry vapor inhalations of beechwood creosote. In many instances, during the past thirty years, I have

known them to be of untold value, combined or not with creosote given internally, in the manner I have indicated.

I have written much and frequently, about this treatment in former years and might not think it desirable for me to write again what precedes, were it not that I wish my convictions to be widely shared, since I know them to be *very* important and not to be ignored by the rising generation of physicians or go unrecorded. We old practitioners have learned some, not to say many, useful lessons from long experience and it is well maybe at times, to give them forth again and again, even at the risk of wearying our readers with a twice-told tale.

As a matter of fact, creosote is to me the only drug, when properly used, which has a very real value in the cure of pulmonary tuberculosis. It will not cure, or even materially benefit all cases, but surely it will greatly help to save some who otherwise are destined to a fatal termination. The reason why creosote is not adhered to, or believed in, as it was at first, now many years ago, is in my judgment simply because it was badly prescribed. Again, that the perforated zinc inhaler is not used in almost all cases as it should be depends simply upon lukewarmness, ignorance, or what is to me, to-day, a great and increasing evil; namely, the far too great respect and following of laboratory, or what is termed *scientific* medicine. But it is not; this is a misnomer.

The only real, useful, practical—indeed scientific, medicine, is what almost wholly depends upon close, accurate bedside observation, always noting results clinically and allowing all mere abstract theories, or even reports of physical instruments of latest finding and doing, influence us very little or not at all.

To complete my brief paper and maybe to the doubting Thomases to help establish in their observation my own convictions, I would cite two men in whose judgment and wide experience I have great confidence.

Dr. J. M. Anders writes in the last edition of his admirable work on Practice (p. 283): "Creosote by inhalation is the remedy par excellence for tuberculous bronchitis combined with spirits of chloroform and alcohol."

In the latest edition of Osler's *Modern Medicine*, Dr. Lawrason Brown states (Vol. 1. p. 504): "Inhalations often markedly benefit the cough, especially when the irritation is in the larger bronchi. The oronasal respirator (Yeo), which can be worn continuously, is probably the best means of administering vapors."

Further, he adds (p. 505): creosote "in some cases seems to act almost as a specific upon the accompanying bronchorrhea and intercurrent attacks of simple bronchitis. For this effect small doses only are necessary in most patients."

Anders also writes that in his experience creosote has helped greatly diminish the fever in tuberculosis. These few but very valuable quotations are surely sufficient to uphold with authority my affirmed and corroborated statements, during many years in which I have had much experience and followed carefully many patients affected with undoubted pulmonary tuberculosis.

42 West Thirty-seventh Street.

THE ADMINISTRATION OF ARSPHENAMINE BY RETENTION ENEMA.

By JOHN L. MANDRACCHIA, M.D.,
BROOKLYN, N. Y.
LATE HOUSE SURGEON, METROPOLITAN HOSPITAL, DEPARTMENT OF PUBLIC CHARITIES, NEW YORK CITY.

The main interest in this report naturally centers in the results obtained by the administration of arsphenamine by retention enema. With the advent of American-made salvarsan, the number of reactions[1] following the intravenous administration of this drug were so numerous that I became more or less discouraged regarding the intravenous route and decided to employ some method whereby we could accomplish the same results clinically and serologically and still avoid the undesirable and sometimes fatal reactions which have occasionally followed the intravenous method of administration. It is not to be inferred that reactions are due to our American product, for some patients have tolerated this domestic product very well when given intravenously, nor is it due to poor technique, for we have observed nitroid crises under the most strict asepsis; then to what is this salvarsan reaction due?

The factors that can cause salvarsan reactions excluding a poorly made product and bad technique are:

1. The possibility that the patient has had some food previous to receiving the drug;

2. A deficient amount of alkaline salts in the body fluids;

3. A low degree of activity from the organs of internal secretion;[2] and last but not least,

4. The probability that the patient has a heart lesion so imperceptible that none of the available instruments can help us in discovering the lesion. These are factors which must be considered and adjusted when one contemplates giving salvarsan intelligently by the intravenous route. To go into further details in the subject of reactions would be to defeat the purpose of this paper, and therefore I shall now enter upon the subject proper.

With the method which will shortly be described no sequelæ such as headaches, nausea, vomiting, fever, dizziness, or subsequent nitroid crises acting destructively upon the eyes, kidneys, liver, or fatal termination have ever been observed. There was only one case of Jarisch-Herxheimer reaction developed in a child with hereditary syphilis thirty-six hours after the administration of the arsphenamine enema. In this case the cutaneous eruption and edema of the face cleared completely in seventy-two hours. This is just about the time when it is believed that arsphenamine is completely eliminated from the body fluids.

From the dawn of salvarsan therapy, syphilographers have tried to administer this powerful drug in such a way that it would not be so obnoxious to the patient. Bagrow[3] of Moscow was the first one to employ suppositories of coca butter with 0.10 to 0.20 centigrams of neosalvarsan. Weil, Morel, and G. Moriquand in 1912 employed glycerin suppositories and their results were very satisfactory, leading them to conclude that the rectal route is the ideal method for the administration of salvarsan and that the intravenous route

may be used only in cases of emergencies. They came to this conclusion after a comparative study of the intravenous, the intramuscular, and the rectal methods. Following these workers came Geley,[5] who was the first one to use the enteroclysis. Rajat[6] was so enthusiastic over his results that he pronounced the intravenous injection a dangerous procedure. Oulman and Wolheim[7] in 1913 also concluded that their results were superior to the intravenous method. Benoit[8] and Guiard,[9] who employed neosalvarsan by rectum, claim that their results were not as good as those obtained by the intravenous method. Last year Boyd and Joseph[10] arrived at the conclusion that their results were just as good as those obtained by the intravenous method, minus the reactions, and that their method was so simple that the whole procedure could be left in charge of a nurse or the patient himself.

At the Metropolitan Hospital, where this work has been carried out, the cases that have been available are of a very low grade character. The majority are prostitutes who have been sent to the hospital from correctional institutions and as a rule meet the treatment only half way. In spite of this difficulty some of them have co-operated with the doctors and the results obtained have been decidedly satisfactory. All cases have the Wassermann taken before, during, and after the treatment. No tests from private laboratories were depended upon, for many and many a time a case which has been declared negative has been found to be positive by our laboratory.

At our pathological laboratory the results of a Wassermann test are based on the combined readings of three antigens: Antigen No. 1—Human heart cholesterin; No. 2—Guinea pig heart cholesterin; No. 3—Guinea pig heart alcoholic extract. Each antigen according to the degree of hemolysis is read off as one, two, three, or four plus, and then the sum total of the three antigens is summed up. One can see then that a very accurate result is thus obtained.

Technique.—1. The patients are given a mild laxative the night before and no breakfast on the following morning. About three hours before the time set for administering the arsphenamine enema, they are given a soap suds enema till the return flow is clear and then urged to evacuate completely.

2. The solution of arsphenamine is prepared in the usual way, observing all the rules of asepsis and diluting it to anywhere between 200 c.c. and 250 c.c. This depends on the size of the individual. Azemar introduces in the solution a few drops of tincture of opium, but for obvious reasons this procedure has always been avoided.

3. The apparatus consists of a glass cylinder of a capacity of about 300 c.c., connected at one end with a rubber tubing having a glass window and a stop-cock and a rectal tube of sufficient calibre so that the fluid can flow easily and swiftly. The tube we employ is No. 30 French. No dropper bulb is necessary for the reason that the solution is to be kept away from contact with air as much as possible. The whole outfit must be sterilized before using.

4. In administering the arsphenamine enema, the position that the patient assumes while and and after the enema is given is very important. The solution having been prepared and placed in the cylinder and the air having been expelled, the patient, if a male, is allowed to assume the genupectoral position, and if a female, the lateral or Sims position, and after the rectal tube has been introduced into the rectum for four or five inches the solution is allowed to flow into the rectum by gravity after the stop-cock in the rubber tube has been opened. As a rule the average patient can hold this enema from twenty to twenty-four hours. In exceptional cases it has been held for four days. Arsphenamine seems to have a constipating effect on the intestinal tract. Where a patient cannot retain the enema, it has been the custom to give a dose of the tincture of opium or paregoric by mouth. In children this is a standing rule. The enema having been given, the patients are sent to bed and allowed to remain in bed for about four hours instructing them to change their position at frequent intervals. Reverse peristalsis can be more readily facilitated when the foot of the bed is elevated.

5. In adults the initial dose is 0.3 gram and every dose thereafter 0.6 gram. The enema can be given either once or twice a week, all depending on the condition of the patient. By giving the enema twice a week it is believed that the spirochetes are kept in a constant arsenic saturation and thus the duration of the infection is materially shortened. The ideal time to give these enemas is in the evening so that one is assured that the patient goes to bed and rests completely in the reclining position.

6. As to the number of enemas necessary in order to effect a cure clinically and serologically there is no absolute rule. Each case is to be treated individually. On an average a case usually clears up clinically and serologically after five arsphenamine enemas. One case I recall cleared up after three enemas. Then again, another case was still four plus after twelve enemas. This latter case, by the way, was one of tertiary syphilis with extensive bone pathology, and it is probable that no amount of arsphenamine, regardless of the method used, could affect the Wassermann test or improve the symptoms. It is not to be concluded that in tertiary syphilis rectal therapy is not of any avail; far from it, for in some cases splendid results have been obtained both symptomatically and serologically. In some of these tertiary cases, at this writing, the Wassermann test has been changed from four plus to two plus, besides improving the symptoms, and with further treatment such cases no doubt will give gratifying results.

7. During the course of arsphenamine enemas, the patient should undergo a course of active mercurial treatment. Unless there are very good contraindications against giving mercury during the arsphenamine treatment, the patients are usually instructed to stop their mercurial treatment on the day that they receive the arsphenamine enema. Of course, in cases of nephritic lesions or pulmonary tuberculosis one naturally must be very cautious as to the procedure of treatment.

Case I.—S. B., age 22, female, colored, admitted to

hospital January 7, 1919, with crustaceous lesions in the face, neck, arms and legs which she has had since last month. On January 11, 1919, the Wassermann reaction was: Antigen No. 1, Human heart cholesterin, four plus; No. 2, Guinea pig heart cholesterin, four plus; No. 3, Guinea pig heart alcoholic extract, four plus. Diagnosis: Positive (four plus). On February 21, 1919, after she had received five injections of arsphenamine intravenously and six mercury hypodermics, the Wassermann reaction was still four plus. In March, 1919, she began to receive arsphenamine per rectum and daily mercurial inunctions.

March 7.—Arsphenamine 0.3 by retention enema. Retained for twelve hours. Complained of only slight gurgling sensation in the abdomen. No pains.

March 24.—Arsphenamine 0.6 by retention enema. Retained for fourteen hours. No complaints.

March 29.—Arsphenamine 0.6 by retention enema. Retained for six hours. No complaints.

April 12.—Arsphenamine 0.6 by retention enema. Retained for eight hours. No complaints.

April 18.—Arsphenamine 0.6 by retention enema. Retained for twelve hours. No complaints.

April 24.—Wassermann reaction negative. May 5, Wassermann reaction negative. May 14, Wassermann reaction negative. The patient was discharged from the hospital, her skin lesions having completely cleared up.

Case II.— M. L., age 19, female, white, married. On admission to the hospital patient had a pustular eruption over the thorax and abdomen and also on the left wrist and left leg. Both breasts were covered with papular syphilides. The labia majora were a mass of chancres. The anal region was full of condylomata. She claims that she first noticed the chancres about four weeks after intercourse. The Wassermann reaction on admission was reported as four plus. Previous treatment: she received mercury salicylate hypodermics weekly and mercurial inunctions daily. While her condition improved with mercurial treatment, the Wassermann reaction on January 31, 1919, was still four plus. She then received the following treatment:

March 7.—Arsphenamine 0.3 by retention enema. Complained of "cramps" for about four hours. Retained enema for ten hours.

March 8 to 13.—Daily mercurial inunctions.

March 14.—Arsphenamine 0.6 by retention enema. No complaints. Skin lesions almost completed cleared up.

March 21.—Arsphenamine 0.6 by retention enema.

March 26.—Wassermann reaction negative. Two other Wassermann tests (April 29 and May 5) were both reported negative.

Case III.—B. M., age 28, female, white. Admitted to the hospital giving the following history: She first noticed a "sore" in the labia majora of the left side, the early part of September, 1918. Three weeks ago she had "sores" breaking out over various parts of her body and complained of headaches, chills, and fever. She then noticed that her hair began to fall, and suffered with sore throat and loss of appetite. Examination: Crustaceous lesions over the forehead, axillæ, on the labia majora, and the mucous surfaces of the vaginal wall, and also in the anal region. These sores were hard, concave, and not painful. The treatment which she received prior to her coming to the hospital was more or less of a desultory nature.

February 21.—Wassermann reaction weakly positive.

February 22 to March 12.—Daily mercurial inunctions.

March 13.—Arsphenamine 0.3 by retention enema. Retained for twelve hours.

March 21.—Arsphenamine 0.6 by retention enema. No complaints.

March 22 to April 18.—Protoiodide of mercury, gr. 1/5 t.i.d.

March 29 and April 12.—Arsphenamine 0.6 by retention enema.

April 24.—Wassermann reaction negative and all cutaneous lesions healed up.

Case IV.—R. U., age 31, female, white. About four years ago, she fell against a tree, striking her leg and six months later she began to have an itching sensation in the area where she struck her leg. She then began to scratch herself and an open sore was the result. She was treated in various hospitals for this sore but it never healed. She denies any venereal disease. The gamut of antiluetic therapy with the exception of salvarsan had been employed in this case but it had failed to heal the ulcer. Wassermann reactions of this case taken between December, 1915, and January, 1918, are here appended. In each reaction only two antigens were employed.

December 10 and 23, 1915, reported negative by Dr. L. H. Cornwall.

April 12, 1916, reported doubtful by Dr. W. W. Hala.

January 7, 1917, and January 5, 1918, reported negative by Dr. W. W. Hala.

On March 7, 1918, after the ulcer had spread considerably, and the leg had reached almost twice the size of the other one, the surgeons did an amputation above the knee. A microscopic examination of the tissue reported by Dr. W. W. Hala: "On microscopical examination, the specimen consists of epidermis and subcutaneous tissue. The epidermis in one area has disappeared by ulceration. Elsewhere the epidermis is normal. The subcutaneous tissue, however, and particularly beneath the ulcerated area shows distinct pathological change. This change consists in an enormous infiltration of small round cells arranged in many areas concentrically around the small blood vessels. The histological appearance suggests granuloma and the lesion is probably due to syphilitic infiltration." Final diagnosis of specimen: Syphilitic ulceration. The stump, however, never healed and finally four weeks later a skin graft was performed which proved to be unsuccessful. On February 21, 1919, the Wassermann reaction was reported as doubtful by Dr. J. G. F. Hiss and Mrs. Williams. In March, 1919, the patient came into my service and the laboratory data which I had collected satisfied me conclusively and I began to give her arsphenamine weekly by retention enema, and protoiodide of mercury 1/5 gr. t.i.d.

March 3, 1919, arsphenamine 0.3 by retention enema.

March 21, 29, April 12, 15, and 18, arsphenamine 0.6 by retention enema.

The Wassermann reactions, using three antigens, were reported by Dr. Hiss and Mrs. Williams as follows:

April 29 and May 14, negative.

May 20, a provocative arsphenamine injection was given by retention enema.

May 21 and 23, Wassermann reported negative.

She retained those arsphenamine enemas from twenty to thirty-six hours. Throughout the course of treatment, the stump has markedly improved and is now almost completely healed.

This is an unusual case and shows how a luetic condition can predispose to malignancy. Czerny and Caan of the Heidelberg Cancer Institute have observed that a very large percentage of these cases have a positive Wassermann.

Case V.—A. M., age 12, female, white. On admission to the hospital she was examined by the oculist and the case was diagnosed as one of interstitial keratitis. The Wassermann reaction was reported four plus. The case was then started on daily mercurial inunctions, atropine to the eyes, and arsphenamine enemas weekly. After two weeks of antileutic treatment she began to have vision from her left eye which progressively improved so that she could walk about the ward and recognize the nurses and patients. After four more weeks of antileutic treatment she showed improvement in her other eye but her serologic test was still four plus. The remarkable feature of this case is that the patient has practically regained her vision without my using the much advocated yellow oxide of mercury which every text-book mentions. In fact, it is well shown that the inunctions and the arsphenamine combined in addition to the atropine have brought joy and happiness into this patient's life.

Analysis of Results.—In the gynecological section of the Metropolitan Hospital, the rectal method of administering arsphenamine has been employed on 25 cases representing the various stages of

syphilis. Five cases, or 20 per cent., have been completely cured serologically and clinically. Nine cases, or 36 per cent., have improved clinically and their Wassermann reactions have been changed from four plus to two plus. In this series is included a patient who recently became hemiplegic and has now regained complete function of her left leg and partial use of her left arm. In 10 cases, or 40 per cent., while the treatment did not affect the Wassermann reaction, the cases showed marked improvement clinically. Some of these cases left the hospital before their treatment was completed when their term was at an end.

When these arsphenamine enemas were first started there was some skepticism as to the possible local injury on the alimentary tract that the drug would produce. As the patients hardly complained we were very much encouraged, until we have now given about 500 of these enemas with no apparent injury to the intestinal tract or the production of any reactions. Its necrotic action is without dispute, but it is readily seen that its action on the intestinal tract is different. Just what the chemical changes that the drug undergoes in the intestinal tract are, is problematical. According to Fleig,[11] salvarsan precipitates into an insoluble albuminate derivative which is not favorably absorbed in an alkaline medium. While this view is an appreciable one theoretically, practically as shown clinically and by the laboratory, it is negligible.

Conclusions.

1. The administration of arsphenamine by retention enema is a successful and practical method of giving this powerful drug and therefore the method demands a place in the therapy of syphilis.

2. The slow absorption is an advantage and prevents the production of nitroid crises.

3. In children it is the method of choice.

4. The contraindications to this method are nil.

5. The results obtained by this method are just as good as those obtained with the intravenous method.

6. What better method can there be where a patient with very fine veins is encountered? How many vein dissections is your patient going to tolerate?

I wish to acknowledge my obligations to Dr. Joseph H. Fobes, the attending surgeon from whose service the cases were selected, and also to the staff of the Metropolitan Hospital for their kind co-operation.

Medicolegal Notes.

Results of Attendant's Negligence.—In an action for alleged negligence against a physician, the evidence showed that the defendant operated on the plaintiff's wife while she was under the influence of an anaesthetic, and after the operation placed her in bed while she was unconscious. He told an attendant employed by the plaintiff to place something warm at or around the patient's feet to relieve her from the shock of the operation. The attendant, an intelligent, competent person, but with no experience as a nurse, placed a hot stove lid on the patient's feet while she was still unconscious, which burned her feet. It was held that the defendant was not liable. The attendant was as competent as he to judge whether the iron was hot enough to burn, and to know that it should not therefore be placed on the patient's feet, and the defendant had a right to rely on this. The doctor's direction to the attendant did not create the relation of master and servant between them.—Malkowski v. Graham, Wisconsin Supreme Court, 172 N. W. 785.

Privileged Communications Statutes.—The Utah statute prohibiting physicians, without the consent of their patients, from testifying in a civil action as to any information acquired in attending a patient which was necessary to enable him to prescribe or act for the patient does not preclude the physician from testifying merely as to the fact of his having been consulted. The statute does not prevent a physician from testifying that he performed an autopsy and as to the result thereof. The privilege claimed does not exist at common law, but was conferred by statute, and in order to be available the claim of privilege must be brought within the clear meaning and spirit of the statute.—Chadwick v. Beneficial Life Ins. Co. (Utah), 181 Pac. 448.

Glanders a Disease, Not an Accident.—The New York Appellate Division holds that the contraction of glanders through inhalation of the bacteria of glanders, while leading a horse affected with glanders through the streets, resulting in the death of a stableman, was not an "accidental injury arising out of and in the course of the employment" wtihin the New York Workmen's Compensation Act. In answer to the argument that such diseases are produced by "external" means, because the bacteria which cause them are introduced into the human body from without, the court said that bacteria are daily received into the body, by contact or inhalation, without resultant disease. The fact of their presence is not the fact of disease. Disease results only from the toxins which the bacteria produce while within the body, and the cause is native, not foreign to that body. The argument would place substantially every infectious disease in the injury class, since in nearly every instance such a disease is produced by bacteria which are the outgrowth of bacteria introduced into the body from without.

Another argument was that in certain diseases the cause is "violent" because of the impact of bacteria when they invade the body. The court considered this reasoning unsound because, granted that there is an impact of bacteria whenever they enter the body, so that accidental injury occurs, then every day of our lives we receive accidental injuries, for daily we breathe in bacteria, or take them into our systems, without resultant disease.—Richardson v. Greenburg, 176 N. Y. Supp. 651.

THE VARIATIONS OF RESIDUAL NITROGEN IN THE BLOOD SERUM.

IT is at present believed that the liver plays a considerable part in the disassimilation of nitrogenous substances. This decomposition begins in the tissues where, under the influence of endocellular diastases, the albumins and nucleoproteins are brought in successive phases to the state of purine bases and amino acids. To this diffuse tissue phase succeeds the hepatic phase. By the action of the liver uric acid is transformed into urea, the amino acids are either directly decomposed into urea or else are dissociated into fatty acids and ammonia. The fatty acids give rise to carbonic acid and water, the ammonia becomes urea. Hepatic insufficiency must therefore result in an imperfect ureogenesis and several methods founded on the analysis of urine have been proposed to place this insufficiency in evidence. They all have the disadvantage of taking as a subject for study urine difficult to collect in totality, still more difficult to guard from secondary changes, and whose composition may be modified by existing renal lesions.

For these reasons Brodin looked to the blood serum for more precise results. He at first studied the variations of the nitrogenous coefficient of the blood serum and found that it was frequently low in cases of hepatic insufficiency, but it was not long before a conclusion was reached that this low coefficient was not to be relied on. It also lacked preciseness, because it varied with the nature of the food taken, a fact which explains the divergence among writers as to its exact determination. The method was unreliable because in the very frequent cases in which a renal and hepatic lesion coexist, the renal lesion overshadows the hepatic lesion, the two lesions acting in an inverse sense, the former increasing, the latter lowering the coefficient. Consequently, observers have been led to study the variations in the residual nitrogen with the following results:

The residual nitrogen of the blood serum is only slightly influenced by the nature of the food consumed. In normal subjects it oscillates within very narrow limits and is always less than 10 centigrams per liter. In subjects with renal lesions, even when advanced but without an appreciable hepatic lesion, the total nitrogen and ureic nitrogen have a higher percentage the greater the renal permeability. The residual nitrogen, on the contrary, remains constant, always less than ten centigrams and, as Widal has shown, almost all the retained total nitrogen in these patients is in the form of urea.

In chronic affections without hepatic changes or action on the general physical condition, the residual nitrogen remains normal, while in all types of hepatic lesions—cardiac liver, advanced cirrhoses, abscess, or cancer—there is an increase in the percentage of the residual nitrogen which appears to be proportional to the extent of the hepatic changes. In acute processes—pneumonia, typhoid fever, tuberculosis—the increase of the percentage of residual nitrogen, although not constant, is met with in a certain number of cases. It would seem logical to admit that the liver has become involved in exactly the same way as the kidneys, so frequently observed during infectious diseases. The special gravity of these cases and the possible appearance of icterus in acute processes, plead in favor of this hypothesis.

Experimental work carried out by Brodin has confirmed his clinical experience. In the dog, after ligation of the ureters, he found an increase of the total nitrogen and ureic nitrogen without any change in the percentage of the residual nitrogen. On the contrary, ligation of the choledochus, complicated with angiocholitis and areolar abscesses, produced a great increase of the residual nitrogen. From these results, he concludes that an increase of the residual nitrogen is dependent upon a morbid change in the hepatic cell. The residual nitrogen is to the liver what ureic nitrogen is to the kidney; its increase in the blood is due to an hepatic lesion while an increase of the ureic nitrogen is the result of renal lesions.

ABDOMINAL AORTITIS.

OUR knowledge of abdominal aortitis has been recently acquired and is due especially to Peter of Paris and to Teissier. From the viewpoint of the etiology there is an important point to be remembered—besides the habitual causative factors of any aortitis—namely the extension of inflammatory processes arising in viscera near the aorta, among which mucomembranous enterocolitis is foremost. The painful manifestations may be explained by irritation of the solar plexus or by vascular disturbances in the form of a local ischemia from arterial spasm or arterial hypertension. So far as the pathology is concerned, the frequency of atheromatous localizations on the abdominal aorta and the relative infrequency of the clinical syndrome of the morbid process are the most worthy of note. The localization of the lesions around the orifices of the large abdominal collaterals, especially of the celiac trunk and superior mesentery, is of particular interest. The intensity of the painful phenomena and the secretory and functional disturbances of the viscera frequently lead to an error in diagnosis, so that

the principal symptoms of the arotic process should be recalled, although they are occasionally difficult to recognize.

It is not always an easy matter to distinguish the syndrome of abdominal aortitis from various disturbances arising from lesions of the celiac and mesenteric collaterals because in reality the various etiological factors are frequently inseparably united. The abdominal syndromes to which vascular morbid processes give rise have an aspect comparable to those which arise in disturbances of the coronary arteries resulting in angina pectoris, hence the name of angina abdominis which has been given them. In fact, it is not too much to say that it is not always possible to distinguish abdominal angina from the pseudogastralgic type of angina pectoris, and in some cases there is an unquestionable identity.

The prognosis of abdominal aortitis should always be guarded, even in the acute forms; in the chronic forms it is invariably serious, death usually taking place at an early date. The diagnosis of this morbid process is far from being always easy as the functional symptoms are prone to lead the physician astray. The physical signs are apt to draw the attention, but it is often impossible to make out when a simple dilatation of the aorta ends and an aneurysm begins. The happy effects of inhalations of amyl nitrite at the time of the paroxysms of pain is likewise valuable from the viewpoint of the diagnosis. Revulsion over the epigastric region will also prove of service in relieving the patient's discomfort.

COLLOIDAL GOLD TEST IN MULTIPLE SCLEROSIS.

LANGE'S colloidal gold test of the cerebrospinal fluid has been of great use in the diagnosis of the various forms of syphilis of the central nervous system and the various curves presented have come to be considered as almost pathognomonic of the conditions with which they are associated. The curve found in general paresis has been obtained in a number of other conditions which are not syphilitic and this fact is of importance and should be well known to avoid errors in diagnosis. Lead poisoning, tuberculous meningitis, brain tumor, and multiple sclerosis are mentioned as diseases in which this form of reaction has been observed. It is apparently inconstant in the first three of these conditions but fairly regular in the last.

Moore has investigated the fluids of twenty-eight cases of which twenty were clinically certain and eight clinically doubtful. He reports (*Archives of Internal Medicine*, 1920, xxv, 58) that in eighteen of the twenty certain cases the colloidal gold test gave a "paretic curve," while in two it was negative. Of the doubtful cases, three gave a "syphilitic curve" and five were negative. In all cases the Wassermann reaction was negative. This association is important, for whatever may be the dispute concerning the significance of the Wassermann when done upon the blood serum it appears to have a high degree of specificity where the spinal fluid is concerned and further it is positive in a large percentage of the cases. It may therefore be said that a "paretic" gold chloride curve and a negative Wassermann on the spinal fluid, together with suggestive signs and symptoms, is highly indicative of multiple sclerosis. In addition to these findings Moore found that eight of his twenty certain cases showed a pleocytosis of from five to seventy cells and thet eighteen of them gave a positive globulin test.

Multiple sclerosis is not always easy of diagnosis and this finding should at times give valuable aid. There is as yet no satisfactory explanation of the colloidal gold reaction. That it is an evidence of the presence of proteins in the spinal fluid is naturally probable but that does not explain the difference in the reaction in different conditions. Much remains to be found out concerning the chemistry of Lange's test but its clinical significance is growing gradually clearer and its place in laboratory procedure is an assured one.

VARIOLATION IN SPAIN IN 1776.

INOCULATION for smallpox was introduced into England in the first half of the XVIII century and the custom quickly diffused itself through Northern Europe—Great Britain, Germany, and Scandinavia—and was maintained up to the time when vaccination succeeded it. The Jennerian resource was promptly adopted in Spain, but it is not generally known that before this epoch variolation was also practised with success. Dr. Lasbennes of Madrid calls attention in *La Medicina Ibera* for November 29, 1919, vol. ix, 108, to an old document which has just come to light from which it appears that on October 31, 1778, Doctor Francisco de Cabarrus, a well known practitioner of the period, made an enthusiastic contribution to the Sociedad Economica Madridense which had reference to variolation carried out by Dr. O'Scanlan in Ferrol and Corunna. The documented report shows that 50 individuals were also inoculated at Madrid by Dr. MacCarthy. The British nationality of the inoculators is readily intelligible, as variolation had existed in England for many years. The original report which was made public by Lasbennes was drawn up and signed by Dr. Maurico Echandi, who was then at the head of the Royal Military Hospital at Corunna. The motivation of the experiment seems to have been the fact that the royal families of England and Germany as well as the King of France and Czar of Russia, with similar notables in other countries, had submitted themselves to variolation as an example to their subjects. It appears, however, that some inoculations had been done in Spain in 1773-4 which had not given good results either in the line of conferring immunity or in assurance against local accidents. It was felt, nevertheless, that such cases were due to defective technique. As an offset it was announced that O'Scanlan who was at the head of

the Marine Hospital at Ferrol had been practising variolation with excellent results since 1772. This official also inoculated a number of subjects in Corunna and the reporter was witness to the inoculation of a series of twelve children in January, 1776. The period of incubation was eight days and the number of pocks in the eruption varied from less than 10 to 30. The disease ran its course briefly without the dreaded suppurative fever. One of the twelve, indeed, developed a general outbreak, but without confluence. The local reaction was undeniably severe, the ulcers sometimes extending to the bone; but this seems to have been anticipated and there were no serious consequences.

Retrospect of the Influenza Pandemic.

Despite the plethora of articles on the subject of the influenza pandemic, many of these are of special value in bringing out new or overlooked data, and until the final account can be written the fragmentary contributions will not be superfluous. In the *Archives Médicales Belges* for June, 1919, lxxii, 6, there is a review of the epidemics of 1918, including influenza. The reviewer uses the term pneumosepticemia to distinguish the fulminating fatal cases which occurred in massed incidence. In France pneumosepticemia first appeared among and for a time was limited to the Senegalese soldiers. It was held at the time that the latter showed a special susceptibility, but this notion was promptly abandoned. The opposite view, that no special susceptibility or immunity existed, held good with some exceptions, one of which was that the young, healthy subject had the least tolerance. The Portuguese steamer *Mozambique* sailed for that colony to repatriate Portuguese colonial soldiers in September, 1918. The disease appeared on shipboard and smote fatally 199 out of 952 passengers and of this number all but 19 were young and healthy soldiers. No less than 43 died within the first 24 hours. Pneumosepticemia in influenza suggests that other form of pneumonia known as plague, but the possibility of identity has never seriously troubled the laboratory men. The author is sceptical of any solid immunity derived from the first wave of influenza, but this point will have to be threshed out later. In regard to plague pneumonia of bubonic affiliations, this was epidemic in China during the winter of 1917-18, but only about 12,000 deaths occurred. The important fact was learned that healthy subjects could act as carriers for this malady. A woman who had lost husband and brothers from the latter, herself escaped infection, but having visited a relative, the latter developed the disease. She then went to other neighborhoods where several more persons developed the infection. It seems therefore certain that either natural immunity exists or that the affection may appear in mild, unrecognizable form.

Rapid Orientation in Reflexes.

The busy practitioner who has to see from 20 to 30 patients at a sitting finds the outlay of time necessary for eliciting the reflexes burdensome. Many patients, however, complain of vague pains and other subjective symptoms, so that the time must be spent and the question becomes one of economic efficiency. In the *Archives médicales Belges* for August 19, 1919, lxxii, 8, Marchal briefly considers this subject. Merely to prescribe a lotion for these cases without any attempt at diagnosis will almost always end disastrously. The patient will not return or he will derive no benefit or upon his next visit there may be a very different picture which has not been foreseen. But it is possible in two minutes' time to explore sufficiently the reflectivity of the subject. The superficial or cutaneous reflexes are of not much value and may be passed over. One should concentrate on the plantar reflex, the tendon reflexes and the forced flexion of the toes with associated flexion of the foot on the leg, leg on the thigh, and thigh on the pelvis. To elicit the tendon reflexes a satisfactory percussion hammer is indispensable. The author insists that the various reflexes of the upper extremity are of importance. By means of these tests we quickly obtain an idea of the integrity or reverse of the pyramidal paths.

News of the Week.

Opposition to Compulsory Health Insurance.—The following resolution was passed by the Medical Association of the Greater City of New York at the regular meeting held January 19, 1920:

Preamble to the resolution: There is now going on in this State a movement to secure legislative enactments establishing compulsory health insurance of the wage-earning class. Such legislation appears undesirable and pernicious for many reasons, and especially for the following:

Compulsory health insurance is contrary to the fundamental principles of Americanism, encouraging class consciousness and being essentially Socialistic and destructive of that individualism which is necessary for best national development. If the medical profession, whose members are naturally highly individualistic, can be Socialized, there is no limit to the extent to which Socialism may be carried in this country. The adoption of compulsory health insurance would be equivalent to the acceptance of Socialism as a universal dogma.

Compulsory health insurance would substitute for the medical care and treatment now received by the wage-earning class, medical care and treatment of an inferior character, thereby doing a positive injury to that class.

Compulsory health insurance would also injure the wage-earning class by practically depriving them of the benefit of the personal relation between patient and physician, the great value of which is universally recognized, both in regard to its effect on the character of medical treatment which patient receives and on the patient's peace of mind.

Compulsory health insurance compels citizens to invest their savings in a certain way, and it fixes the remuneration of a class of special workers (physicians, dentists and nurses) without their consent.

Compulsory health insurance would practically

deprive the wage-earning class of the free choice of their medical attendant.

Compulsory health insurance would impose on the wage-earning class the annoyance of extensive inquisition into their private affairs by Government officers and agents.

Compulsory health insurance would impose a heavy financial burden on the community.

Compulsory health insurance would damage the medical profession both morally and materially. It would change the character of the occupation of those who participated in it from that of a learned and noble profession, which to a considerable extent is its own reward for hardships and poor financial returns, to a poorly paid, poorly esteemed trade characterized by drudgery and routinism and an appendage to a political machine; and it would, as a preliminary measure, confiscate what is of the nature of property, viz., the medical practices of the physicians, to acquire which they have in many cases worked for years, and from which they derive their incomes.

Compulsory health insurance would lower the general standard of medical practice and the personal standard of the medical profession.

Compulsory health insurance would be a potent factor in checking the advance of medical science.

Compulsory health insurance, by making the profession less attractive, would drive many now practising it into other occupations, and would discourage many from taking it up.

Compulsory health insurance would invite malingering and idleness.

Compulsory health insurance has proved a comparative failure in Germany and Austria where it has been in existence for a generation, and where the character of the people and of the institutions make the field more favorable for it than the character of the American people and institutions. It has also proved far from satisfactory in England.

In view of the facts herewith mentioned, *Be It Resolved*, that The Medical Association of the Greater City of New York is thoroughly convinced that compulsory health insurance as we now understand it is both undesirable and pernicious, and that legislation to establish it should be and hereby is condemned absolutely, without reservation.

Committee, George L. Brodhead, M.D.; Nathan B. Van Etten, M.D.; Robert E. Coughlin, M.D., *Chairman;* Edward E. Cornwall, M.D., *President.*

First Congress of the Association of French-Speaking Gynecologists and Obstetricians.—This society recently held its first session at Brussels. The two French national societies, one devoted to obstetrics and the other to gynecology, obstetrics, and pediatrics, which flourished before the war, were also open to members in French-speaking countries. But as far back as 1913 the two national societies were amalgamated under the presidency of Pozzi, under the name of the Association of French-Speaking Gynecologists and Obstetricians. The Belgian and Swiss national societies devoted to the same branches were affiliated and the first session of the newly consolidated body was to have been held in October, 1914, at Lyon. Five years elapsed, however, before the meeting actually took place, as above stated. The newly organized body is a federation of older societies. The Belgian national society, which is one of the federated bodies, naturally took over the organization and supplied all the executive officers. The countries represented in the federation were France and colonies, Belgium, and French Switzerland. The majority of the distinguished guests came from Italy and Spain, and the significance of this fact is deeper than is at first sight apparent, for Professor Pestalozza of Rome, in the course of the closing address of the meeting, referred pointedly to Latin confraternity and the attempt to place the Latin culture at the head of civilization. The proceedings of the first Congress are published in the *Revue Française de Gynécologie et d'Obstétrique* for October, 1919, xiv, 10.

Centenary of a Great Medical Journal.—With the January issue of the present year *The American Journal of the Medical Sciences* completes one hundred years of uninterrupted existence, being, with one exception, the oldest medical periodical published in the English language. It was founded under the editorship of Dr. Nathaniel Chapman in 1820, and has enjoyed continuous publication since, through periods of war as well as peace.

Increase in Hospital Pay Patients.—In its fortieth annual report, for the year ending September 30, 1919, the United Hospital Fund of New York announces that the proportion of free patients has decreased 16 per cent during the last eight years, while the proportion of patients who pay all or part of the ward rate has increased 17 per cent. The United Hospital Fund began in 1879 with nineteen hospitals, caring for 8,688 patients during the year, with receipts amounting to $26,455.07. During the last year the organization gave support to forty-six hospitals, which cared for 147,422 patients, and gave 2,443,562 days' treatment, with receipts amounting to $221,535.34. It now costs about $9,500,000 a year to maintain and operate the forty-six United Hospitals. Payments for treatment amount to $5,000,000, and incomes from endowments amount to $1,500,000, a total of $6,500,000, making necessary annual gifts amounting to $3,000,000. This amount, however, has never been raised in a year, the recent drive for $1,000,000 bringing in something over $900,000. The average cost per day for ward patients was $2.06 two years ago, and $2.69 last year, an increase of 30 per cent.

Fund for Student Nurses.—A gift of $50,000 was recently made to Mt. Sinai Training School for Nurses by William D. and Frederick Scholle, in memory of their father, Albert W. Scholle, who was once president of the school.

Classes for Hard of Hearing.—Under the direction of the Board of Education of New York City special free classes in lip reading for men and women who are hard of hearing are held in the Evening School 93. Special instruction is given also for those who stammer and lisp.

Reports of Too Early Discharge of Tuberculous Soldiers Denied.—The reports recently circulated

in certain newspapers regarding the alleged discharge from army hospitals before cured of the disease have been denied by Major-General Meritte W. Ireland, Surgeon General of the Army. No man, he declares, is discharged until the medical department has done everything for him which it can do. No man is discharged, if he is not in condition to care for himself, until arrangements have been made to turn him over to the War Risk Insurance Bureau.

Nursing Course in New York University.—New York University will include in its curriculum for the next semester, beginning in February, a course in industrial nursing. The course, which forms a part of the work of the School of Commerce, will be given by Miss Elizabeth Hallam Bohn.

Midwives Attend One-Sixth of All Births.—That midwives attend 16 per cent of all births and 35 to 40 per cent of all foreign births is the statement made recently by the New York State Department of Health. In this country few restrictions have been placed upon the practice of midwifery, with the result that many unqualified women have entered the field, have not been able to meet even ordinary emergencies, and have thus thrown this occupation into disrepute. In order to help to prevent the many unnecessary deaths of babies and mothers at or immediately after childbirth, the State Department of Health has required the licensing of midwives since 1914. This has resulted in driving out of business most of the incompetent and unfit, and of raising the standard of those who have shown themselves qualified to practise. Licenses are renewed annually and any midwives who have had charges made and proved against them lose their right to practise if it can be shown that they have violated the health regulations or are incompetent. In the case of grave offenses the license is revoked.

Strange Disease in Oklahoma.—A disease, thought by some physicians to be a mild form of cholera, has appeared in Oklahoma City, Okla., where 500 of the inhabitants are ill with the strange malady. Several deaths have occurred. The State Health Department has sent physicians and inspectors to the town to investigate the epidemic.

To Study Measles.—Dr. Royal S. Copeland, Health Commissioner of New York City, has requested Dr. William H. Park, Director of the Bureau of Laboratories, to undertake the serious study of measles. During the first ten days of January more than two thousand cases of measles were reported, an unusual number for this season. The statistics of the Department of Health show that there were 8,194 cases in 1919, with 218 deaths; 28,675 cases in 1918, with 790 deaths; 27,419 cases in 1917, with 516 deaths, and 21,603 cases in 1916, with 490 deaths.

Encephalitis Lethargica in London.—According to cable dispatches, several cases of encephalitis lethargica are under treatment in the London Hospital. The chief symptom is sleepiness, in these cases, yet the disease has nothing else in common with the "sleeping sickness" of Africa.

Dr. W. E. List, assistant superintendent of the Cincinnati General Hospital, has been elected superintendent of the Minneapolis City Hospital, to succeed Dr. Herbert O. Collins.

Dr. Herman M. Biggs, of New York, has been reappointed by Governor Smith as State Commissioner of Health.

Medical Fraternity Meets.—The bi-annual convention of the Chi Zeta Chi medical fraternity was held the first week in January at the Piedmont Hotel, Atlanta, Ga. Nearly a hundred delegates from all sections of the United States attended.

Medical Society Elections.—THE AMERICAN SOCIETY FOR THE CONTROL OF CANCER, at its annual meeting, New York City, November 5, elected Dr. Charles A. Powers, of Denver, Colo., to succeed the late Dr. George C. Clark, the first and only President of the Society. Sir Arthur Newsholme, the eminent British sanitarian, now Director of the School of Hygiene and Public Health of the Johns Hopkins University, was elected as the Society's first Honorary Vice-President. Dr. Francis Carter Wood, of New York City, and Dr. Robert B. Greenough, of Boston, were elected to fill the vacancies in the Executive Committee created because of the increase of the committee from thirteen to fifteen. Dr. Edward Reynolds, of Boston, and Mr. Thomas M. Debevoise, of New York City, were re-elected respectively as Chairman and Secretary of the Board of Directors. The election of Vice-Presidents and other officers was referred to the Executive Committee, with power. The Board of Directors approved the action of the Executive Committee in appointing Mr. Frank J. Osborne as Executive Secretary of the Society to succeed Mr. Curtis E. Lakeman.

THE BUCHANAN COUNTY (KAN.) MEDICAL SOCIETY, at its annual meeting, December 3, elected the following officers for the ensuing year: *President,* Dr. L. J. Dandurant; *First Vice-President,* Dr. H. S. Conrad; *Second Vice-President,* Dr. T. M. Paul; *Secretary,* Dr. F. X. Hartigan; *Censor* 1920-21-22, Dr. F. H. Ladd; *Delegates* to the State Society, Dr. Daniel Morton and Dr. Floyd Spencer.

THE SOUTHWEST VIRGINIA MEDICAL SOCIETY was reorganized at a recent meeting, after a lapse since 1916. The reorganization was effected under the State Medical Society, in accordance with the laws of the American Medical Association. The following officers were elected for the ensuing year: *President,* Dr. W. R. Cushing, Dublin; *Vice-President,* Dr. J. A. Noblin, Radford; *Secretary-Treasurer,* Dr. A. B. Greiner, Rural Retreat.

THE FORSYTH (NORTH CAROLINA) MEDICAL SOCIETY at a recent meeting elected the following officers for the coming year: *President,* Dr. S. D. Craig; *First Vice-President,* Dr. Frederic M. Hanes; *Second Vice-President,* Dr. W. L. Grimes; *Secretary,* Dr. V. M. Long.

THE DOUGLAS COUNTY (MINN.) MEDICAL SOCIETY, at its annual meeting December 10, elected the following officers for the ensuing year: *President,* Dr. W. E. McEachern; *Vice-President,* Dr. C. B. Ridell; *Secretary-Treasurer,* Dr. J. C. Kyllo; *Censor* (three years), Dr. G. H. Conklin; *Delegate,* Dr. L. A. Potter.

THE BALTIMORE CITY MEDICAL SOCIETY, at its annual meeting December 5, elected the following officers: *President,* Dr. Harvey B. Stone; *Vice-*

President, Dr. Edward A. Looper; *Secretary,* Dr. Frank S. Lynn; *Treasurer,* Dr. Charles E. Brack. The retiring president, Dr. Guy L. Hunner, was appointed a member of the board of censors.

THE SOUTHERN MINNESOTA MEDICAL ASSOCIATION, at its annual meeting held in Mankato December 1 to 4, elected the following officers for the coming year: *President,* Dr. Herbert Z. Giffin, Rochester; *Vice-Presidents,* Dr. Archa E. Wilcox, Minneapolis, and Dr. Walter J. Richardson, Fairmont; *Secretary,* Dr. Henry T. McGuigan, Red Wing (re-elected); *Treasurer,* Dr. George F. Merritt, St. Peter (re-elected).

THE OKLAHOMA COUNTY MEDICAL SOCIETY, at a meeting held December 20, elected the following officers: *President,* Dr. Horace Reed; *Vice-President,* Dr. J. S. Hartford; *Secretary-Treasurer,* Dr. Tom Lowry.

THE TRI-STATE MEDICAL SOCIETY, at a recent meeting held at Marshall, Texas, elected the following officers for the coming year: *President,* Dr. C. R. Hargrove of Marshall, Texas; *Vice-Presidents,* Dr. L. H. Lanier of Texarkana, Texas, Dr. H. W. Jarrell of Mansfield, La., and Dr. Joe Becton of Greenville, Texas; *Secretary,* Dr. F. H. Walke, Shreveport, La.

THE WHITEFIELD COUNTY (GA.) MEDICAL SOCIETY, at its meeting held in December the following officers were elected for the coming year: *President,* Dr. H. J. Ault; *Vice-President,* Dr. H. L. Erwin; *Secretary-Treasurer,* Dr. B. L. Kennedy.

THE POLK COUNTY (IOWA) MEDICAL SOCIETY, at its annual meeting, December 23, elected the following officers for the next year: *President,* Dr. Channing Smith; *Vice-President,* Dr. Charles F. Smith; *Secretary,* Dr. Thomas F. Duhigg; *Treasurer,* Dr. E. B. Mountain.

Obituary Notes.—DR. BRITTON D. EVANS, Superintendent of the State Hospital for the Insane, Morris Plains, N. J., died in that institution on January 14 of heart disease. He was born in Bridgetown, Md., in 1858, and he was graduated from the College of Physicians and Surgeons, Baltimore, in 1885, specializing in diseases of the mind and nervous system. Dr. Evans first became known to the medical profession and the public at large through his connection with the trial of Harry K. Thaw for the murder of Stanford White, when he added the suggestive term "brainstorm" to psychiatric terminology. He was a member of the American Medico-Psychological Association, the American Medical Association, and other scientific bodies, and was a frequent contributor to the literature concerning mental and nervous diseases.

DR. C. C. MADDOX of Alpharetta, Ga., died in a sanatorium in Atlanta, January 6, at the age of 61. He was graduated from Oglethorp Medical College, Savannah, Ga., in 1880.

DR. JOSHUA R. WEEKS of Brooklyn, N. Y., died January 12, in his sixty-fourth year. He was graduated from the University of Buffalo Medical Department in 1877.

Dr. HOMER ANDREW BUSHNELL, of North Adams, Mass., died December 30, in the Westfield State Sanitarium, where he had been under treatment for a complication of diseases for a number of months. He was 40 years of age. Dr. Bushnell was graduated from Albany Medical College in 1905.

Correspondence.

INFLUENZA AND SINUSITIS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—May I ask you to give this letter space in your correspondence column? The following points may not be without interest at the present time:

1. In the MEDICAL RECORD of May 27, 1917, I published an article entitled "Epidemic Nasal Sinusitis; Influenza and Grippe Its Misnomers." I enclose a copy of it to you, in which the marginal notations represent what I consider a two-year discount of every acknowledged happening in the late epidemic, including the latest monkey experiments.

2. In the *Boston Medical and Surgical Journal* of Nov. 28, 1918, under Correspondence, I described Spanish influenza as an acute mucous sinusitis. I also described the path of infection as I then conceived it. I know now that while this was true, it was not the whole truth.

3. In the late epidemic the suddenness of attack and collapse were conspicuous features, and they were the main objections raised to my contentions. A man went down town in the morning apparently well. An hour or so later he stepped into the telephone booth and collapsed.

4. These objections were not sound. Constitutional absorption from an infected nasal sinus may be divided into two stages, (1) Acute, (2) Chronic. The acute stage ensues immediately upon infection of the mucous membrane, and the path of infection is by blood stream and lymphatic system. Formerly I thought only the latter was involved. Chronic absorption takes place when the cavity is filled with secretion. In this case we also have to deal with overflow into the nose and throat. This is a late stage.

5. Very briefly the key to the nasal sinuses is the lateral nasal wall. One predicates the other. Their mucous membranes are continuous and their blood supply one and the same (Zuckerkandl, Hajek). The nasal sinuses, therefore, are either continuous with, formed by, or incorporated in the lateral nasal wall.

6. I applied the phenol-sulphone-phthalein test to this wall at various places in order to determine the rapidity of absorption from this region. I injected it submucously because this was the nearest approach which I could make to the method of actual infection *i.e.* direct attack on the membrane. Following the rules for this test I was able to get the dye in the urine, by natural micturition, in the average time of 20 minutes. Had the ureters been catheterized the time would have been shorter. If one considers the lung a half-way station, it is probably passed in 10 minutes. This is a preliminary statement, and I intend to do more along this line. I have seen enough to know that rapidity of onset is not a valid objection to my contention.

7. Considering the disease, influenza, as it was described in the literature prior to 1918, all authorities from Weichselbaum to Osler were agreed that purulent nasal sinusitis was a constant factor. Back in 1906 I first discovered that this was the only admission of constancy in this kaleidoscopic disease. Constancy means 100 per cent. Purulent nasal sinusitis was, therefore, an essential, not a com-

plication. Its presence or absence supplied the acid test as to whether a suspected victim, man or monkey, had influenza or not, because all authorities were agreed that it was constant.

8. But nasal sinusitis is a distinct disease with distinct symptomatology. Its picture from onset to the final encephalitis lethargica cannot be distinguished from the symptomatology of influenza. Furthermore nasal sinusitis has always conformed to Koch's laws. To infect a nasal sinus and in this way to fulfil the third law of Koch is a very simple matter.

9. When Spanish influenza came along I immediately looked for my constant factor, purulent sinusitis, and it was absent. I no longer had influenza; I had something else. But if nasal sinusitis was an essential to the picture I probably had it in another form, with no change in substance. I then described Spanish influenza as stated above, and all autopsy reports and authorities have sustained my contention that the sinusitis was present in its mucous form. This confirmation was macroscopic, whereas it should have been microscopic.

10. What is the most common invading agent in nasal sinusitis? By common consent the *B. influenzæ*. It has a specific, selective, infective affinity for the nasal sinuses, just as the virus of anterior poliomyelitis has for the anterior horns of the spinal cord.

11. Sporadic and endemic nasal sinusitis may have other invading organisms. In epidemic and pandemic nasal sinusitis the invading organism is the *B. influenzæ*.

12. To me the term influenza with or without qualifying adjectives remains a misnomer.

P. S.—Since writing the above I have completed a most severe test on the nasal sinuses with regard to constitutional absorption. The antrum, because of its anatomical position, with the head upright, and the fact that its ostium is at the top, not at the bottom, as is the case with the other sinuses, is admitted to be opposed to gravitation, therefore less likely to overflow and empty itself.

Taking exactly 1 c.c. of standard phenol-sulphonephthalein solution I punctured the antrum with a needle, having first sealed its ostium with cotton, and dropped the solution into the cavity. Withdrawing the needle I sealed its point of entrance. This was not a fair test because I did not have the advantage of multiplication and manufacture, which are the properties of the *B. influenzæ*. Nevertheless I accepted battle. The patient was instructed to save a 24-hour specimen of urine, which amounted to two quarts. I had to find the dye in a two-quart solution, and this time whatever dye was found in the urine was the direct result of mucous-membrane absorption. It was not injected submucously. I found it. This means that sometime within 24 hours secretion can be absorbed from the nasal sinuses. In such a dilution, and by this method the reaction is not as strong as otherwise, and is best found in the meniscus after addition of sodium hydroxide and shaking.

This is an example of chronic (?) absorption from the nasal sinuses and rather revolutionizes even my radical ideas.

JOHN J. HURLEY, M.D., F.A.C.S.

194 BAY STATE ROAD. BOSTON, MASS.

A NEW REMEDY FOR INFLUENZA?

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Epidemic influenza has made its appearance again and thousands of new cases are reported daily. We do not know of any prophylactic measures to ward it off or prevent it from spreading, nor do we know its origin, and we are just as ignorant in regard to its treatment. Most people afflicted with it get well in spite of any treatment. We are unaware of any specific which will cure it. Vaccines and serums have been useless.

Under these circumstances you will pardon me for suggesting a remedy which may be of great benefit. I was told of this remedy by a noted chemist, well known throughout this country. He informed me that during the great epidemic in the fall of 1918 *none* of the thousands of men and women regularly employed in the Edgewood arsenal in Maryland contracted influenza, although there were hundreds of cases in the immediate neighborhood among people not employed at the arsenal. Chlorine gas was manufactured at the arsenal for war purposes and all the employees inhaled minute quantities of this gas every day. The chemist referred to above attributed the immunity to influenza of the employees to this inhalation of chlorine gas, and I see no reason to disagree with his conclusions.

Chlorine gas in minute quantities is not dangerous nor deleterious to health. Physicians are advised to use it for disinfecting themselves after visiting contagious diseases. Anders' "Practice of Medicine," 13th edition, page 204, gives the method of generating the gas, which is briefly as follows: Into a saucer place one level teaspoonful of potassium chlorate and add two teaspoonfuls of commercial hydrochloric acid. This will effervesce and a small amount of chlorine gas will fill the room.

As a prophylactic measure each household could generate and inhale this gas for fifteen minutes every evening. Those already attacked by influenza could take three or four inhalations during the day for about fifteen minutes at a time. I have repeatedly disinfected myself in the above manner after visiting contagious diseases and cannot see how any harm can result from trying it on influenza cases. Patients should keep at least six feet away from the saucer, as the gas is very strong before it gets mixed with the air.

One of my patients worked in the fall of 1918 in a munitions factory employing about 3,500 women. It was noticed at the time that very few cases of influenza developed among them. Inquiry elicited the fact that every Saturday evening the dressing rooms and toilets were disinfected. When the employees came to work on Monday mornings they noticed a strong, pungent gas in the dressing rooms and toilets. I made some chlorine gas by the method previously described and the patient identified it as the same as that in the factory. It seems, therefore, that a weekly disinfection materially reduced the number of cases. A friend informed me recently that a physician in New Jersey used chlorine gas during the influenza epidemic last year, and not only did not lose a case, but that all his patients recovered in an incredibly short time.

Considering the above facts, chlorine gas in small amounts should be given a trial. It can do no harm

if used cautiously, and it may do a great deal of good. It is high time that a systematic investigation of the immunity of workers in certain industries be undertaken to determine the cause of that immunity in order that it may be applied as a remedy in the treatment of diseases.

F. TWEDDELL, M.D.,

GREAT NECK, N. Y.

LETTER FROM PARIS.

PARIS, January 1, 1920.

Trypsin Intravenously.—Trypsin has often been advised in the treatment of malignant neoplasms, but when exhibited *per os* it appears to have little activity and when given subcutaneously it frequently provokes violent reaction and painful sloughing. Loeper of Paris has had the happy idea of resorting to intravenous injections of trypsin, using a 5 per cent. or 10 per cent. solution in pancreatin water, filtered on a porcelain filter or tyndallized. From all I can learn these injections are inoffensive and were first of all used in the most varied types of cancer—of the ovary, tongue, breast, uterus, and intestine, usually without any results whatever, while occasionally they were, to say the least, bad. On the other hand, they were better—sometimes very appreciably so—in cases of gastric cancer.

Loeper had had five cases under treatment. One was an epithelial neoplasm of the mucous type, located on the posterior aspect of the stomach, and accompanied by mesogastric symptoms; three others presented extensive pyloric cancers, extending to the antrum and lesser curvature, while the fifth subject presented a pyloric cancerous stenosis with gastric dilatation and retention. One of these cases was in no way benefited by the treatment; the stenosis was very narrow, vomiting was constant, and the peritoneum, liver, and lymph nodes were the seat of metastases, which naturally accounts for the unsuccessful results. Another patient died after four months of a veritable resurrection, because from the very onset of the treatment there was a pelvic generalization and a neoplastic infarct of the spleen. The three other cases were distinctly ameliorated. One of them underwent gastroenterostomy without resection of the pylorus and during five weeks, in spite of substantial feeding, he gained only four pounds in weight; after receiving thirteen injections he gained eleven pounds; the weight then remained stationary, but when the injections were resumed he added another two pounds. In the remaining two cases the patients put on weight: in one case five pounds and a half after thirty-five injections of one centigram each, and in the other six pounds after twenty-three injections. An increase of the appetite was also noted and, above all, an increase in the globular resistance was noted in the blood, likewise an increase of the antitryptic power as well as the percentage of red blood corpuscles and hemoglobin.

It would seem that the intravenous injection of one to two cubic centimeters of pancreatic extract really exerts a favorable action on certain symptoms of gastric cancer. It is probable that trypsin has no direct action on the neoplasm, but it undoubtedly gives rise to an increase of the antiproteolytic power of the blood serum, as well as an augmentation of the globular resistance and the number of erythrocytes. It therefore acts as an antigen, developing the reactions of defense of the organism, and because of this it should find a place in the medical treatment of gastric cancer.

Memorial to the Medical Martyrs of the War.—During the late war the medical corps of France suffered cruelly, and as is only right, this admirable holocaust should be forever commemorated. Many projects have been advanced for the commemoration, but up to the present the Faculties of Medicine has not offered an opinion. It is, however, known that negotiations were under way and certain arrangements had been agreed upon, but all this has been rather vague. Now that the Dean of the Faculty of Paris has spoken it is assured that the glorious dead will be honored as they should be. It only now remains for the public powers and generosity of all to carry out the plan. It has been agreed that a commemorative monument shall be erected in Paris not far from the School of Medicine. Divers projects have been put forward, but there is one particularly seductive, because it will have the twofold advantage of escaping from the too current vulgarity in these kinds of manifestations and to unite the past with the present. There exists at the Rue de l'Ecole de Médecine at Paris a very fine vestige of the old School of Surgery, namely, its amphitheater, at present wedged into the School of Decorative Arts and which is menaced with being demolished. Now, all this part of the old Latin quarter is soon to undergo an entire transformation. The buildings of the Art School will have to be considerably enlarged, thus extending to the Boulevard St. Michel, and the new construction will end in a little square at the corner of the Rue de l'Ecole de Médecine and Rue Racine. It has been proposed to demolish the amphitheater of the School of Surgery stone by stone and then to rebuild it in the square and thus it will be made a kind of temple where, on marble slabs, will be engraved the names of physicians and students of medicine who died for their country. The plan is a dignified one and should be carried out without too long a delay.

Nervous Complications of Parotitis.—The nervous complications of mumps are usually meningeal syndromes, but true paralyses are rare, so that a case recently observed by Lortat-Jacob and Hallez is worth while recording. The patient was a young man of eighteen years who was treated for mumps in March, 1919, and at this time presented an orchitis and dysuria for a week, requiring the use of the catheter. During his stay in hospital, the patient noticed that his legs were weak, to such an extent that he could not stand. However, when he was discharged he could walk almost normally, but he became quickly tired. But in a few days the paresis of the lower limbs recurred, without pain, and the motor disturbances increased to such a degree that the patient was obliged to remain in bed. It was in these circumstances that he came under the observations of the two physicians referred to, on May 27, 1919. At this date an incomplete limp paraplegia was found. The patient could sit on his bed without the help of his legs, but with much difficulty. The left foot was in slight equinism, the muscles of the leg, particularly the extensors,

were deprived of any strength and all attempts at standing were futile. Except these signs, the patient seemed normal, excepting that the tendon reflexes were weak on both sides. There were no disturbances of the sensibility and the general state of health was satisfactory. Galvanoparadisation was begun and, given that there was a marked hypertension of the cerebrospinal fluid, several lumbar punctures were made. By June 7 the patient could take a few steps by dragging the feet, while three days later he could walk alone, and all that remained of the paraplegia were diminished reflexes on the diseased side and the persistency of Babinski's sign. The observers regard this case not as a polyneuritis, although most writers include nearly all instances of paralysis resulting from epidemic parotitis under this heading, but as having a meningeal origin.

3. A Note on the History of Epidemic Encephalomyelitis. F. G. Crookshank.

2. Diagnosis of the Lesions of the Nervous System Produced by Violent Explosions in Close Proximity without External Lesions.—Tom A. Williams holds that the name commotion has been used without sufficient precision, being applied equally to the result of physical disturbances of the nervous system and to the syndrome which occurs on account of the psychic impression caused by the explosion. Certain observers make a diagnosis of hysteria in all cases where explosion has not produced visible wounds or where neurological examination has not revealed organic lesion. The tendency to such diagnosis is due to the fact that a large proportion of the cases recover in a few weeks or even days after violent concussion. However, that this generalization is quite unjustified is proven not only by the considerable number of instances where patients whose symptoms have been thought purely hysterical have developed shortly afterward definite physical signs which at first were absent, but also by the results of experiments with animals subjected to violent explosions. In a series of experiments producing concussion on rabbits results were as follows: Animals in a large meshed cage showed only slight and evanescent stupefaction. Rabbits which were in a ditch and subjected to explosion evidenced dyspnea from the gas remaining in the trench. When the animals were suspended above the level of the residual gas some of them showed no symptoms, others were depressed and inert, while others showed marked excitement, one of them fleeing in screams whenever approached. But in nearly all there was an increased respiratory rate for half an hour. There was no correspondence between the first symptoms and the progress of the case; for instance, an animal which would lie inert with contracted pupil would appear quite well the next day, while another which seemed much less affected died the following day. Two animals which seemed to recover completely within a day died eight and thirteen days later. The most manifest and rapidly ascertained signs of commotion in the human subject are the general muscular relaxation, including that of the face, the muscles of the hands and the hypotentions of the pulse, the dilated pupils and the diminished reflexes, both tendinous and cutaneous. The only one of these symptoms which can be simulated is the general muscular relaxation, but this is not the kind of reaction which simulators are apt to attempt to imitate. This condition may be quite temporary. In order that the prognosis be made quickly it is advisable to examine the cerebrospinal fluid. If, after twenty-four hours, no excess of albumen is found the diagnosis of commotion can be excluded. The presence of albumen, on the contrary, should forbid the sending of the patient back to duty, although he appears functionally to have recovered. Its presence is believed to be due to damage of the choroid plexus, which permits the transudation without diapedesis of leucocytes. Indeed, the lesions may be severe enough to permit of the transudation of erythrocytes, in which case there will be a yellow tint of the spinal fluid. One fallacy in relation to this diagnosis is that in conditions of chronic compression, such as result from tumor or hematoma, there is usually an albuminosis of the spinal fluid. Hyperemotivity is particularly frequent in the milder cases of emotion. In some cases this may be purely psychogenetic reaction, the man's accident imbuing him with a terror of the future. But in some cases it is due to cerebral sideration. In this case it is nearly always accompanied by clearly perceptible vasomotor modifications in the head. The congestion aggravated by posture or excitement is seen conspicuously in the superficial palpebral and sclerotic veins. It is often conspicuous, too, in the temporal artery and the large veins of the neck. There is, often, a widening of the eyelids and a prominence of the eyeballs which remind one of the aspect in Graves' disease, especially when the patient shows a tachycardia, which is often the case. But other ocular signs of hyperthyroidism, fine tremor, hyperhydrosis, emaciation, the gastorintestinal symptoms do not appear. The symptoms which do occur may be attributed to damage of the sympathetic nerves in the head. They are even very persistent, lasting for years, and they occur in cases where hyperemotivity is not a conspicuous feature at all. This persistence contrasts with the usually rapid disappearance of the hyperemotive syndrome in the patients in whom it has occurred merely as a result of excessive fatigue or of disease. Finally, one has to consider the cases in whom a hyperemotivity has been fostered by the patient's own mental attitude. The occurrence of such cases is dependent upon the general attitude of the medical corps towards the phenomena of pithiatism, and their power to distinguish accurately between (1) the cases due to lesions, (2) the cases where a real hyperemotivity exists, (3) the cases where pithiatism is the predominent or sole feature. The differential diagnosis of the syndrome of hyperemotivity and anxiety from that of cerebral commotion and that of pithiatism is given in tabular form.

5. A New Conception of Asthma.—Mark I. Knapp returns to this subject, discussed previously in the MEDICAL RECORD of March 8, 1919, xcv, 10. He says he was led to his present conception of asthma through an experience with four cases, the first one observed seventeen years ago, in which he was consulted for stomach trouble by patients who were also subject to asthma. These patients suffered from insufficiency of the pylorus. Cure of the asthma in the first three cases he ascribed to mere accident, but after the fourth case he came to the conclusion that there must be an intimate connection between asthma and the insufficiency of the pylorus. In the majority of cases of insufficiency of the pylorus there is increased intraabdominal pressure, which is due to increased gas formation in the gastrointestinal tract. The pylorus is more or less relaxed, that is, the sphincteric action of the pylorus is weakened, has become insufficient to act normally. The degree of the insufficiency varies from a slight relaxation to complete patency of the pylorus, when there is no transition noticeable between the stomach and the

duodenum. The result is that the food leaves the stomach in a way which is not intended by nature. There is only one result possible and that is that the patient sooner or later will suffer. The food which should have been acted upon by the stomach and undergone acid digestion gets into the intestine where the digestion is alkaline. It stands to reason that chemical changes contrary to the normal will follow and these are accompanied by gas formation in excess. Both the patency of the pylorus and the increased gas distention can be visualized by the fluoroscope. The increased intraabdominal pressure forces the diaphragm upward against the lungs, which are interfered with in their normal expansion. This interference continues for weeks, months and years at the rate of eighteen times a minute. Such continued interference with the pulmonic function is bound to have a bad effect upon the lungs and the resulting bad effect manifests inself as the clinical picture which we have designated as asthma. Therefore, when the patient had been cured of the gastroenteric trouble and the abdominal pressure again became normal, the lungs had no more obstruction, and so the asthma was cured. The soundness of this theory, which the writer first promulgated in 1902, has been proved in over 400 cases. The treatment is discussed under three heads: (1) treatment of the paroxysm; (2) medicinal treatment of the asthmatic constitution; (3) dietetic treatment of the asthmatic constitution. The best and quickest relief for an attack is washing out the stomach. The medicinal treatment of the asthmatic constitution has for its object the remedying of the underlying cause, which is first the insufficiency of the pylorus. Of chief importance is the diet, for without the proper regulation of the diet one cannot hope to cure asthma.

4. An Outbreak of Botulism.—Charles G. Jennings and his associates in this study, after reviewing the case of botulism which recently occurred in Michigan as the result of eating ripe olives, and discussing the symptoms and diagnosis, outline the serum treatment employed. Antibotulinus serum was obtained through the kindness of Professor Robert Graham of the University of Illinois. Forty-two c.c. of the serum were administered intravenously in one case forty-eight hours after the initial symptoms. It did not affect the disease. Another patient received 10 c.c. of antiserum intravenously forty-eight hours after the initial symptoms, and twelve hours later 10 c.c. were given subcutaneously. The illness of this patient was very mild, and they could not state that the serum had any influence on her recovery. To be of value the serum must be administered early. This can be accomplished only by an early recognition of the disease and by having depots of serum in various centers about the country. The dosage has not been fully established. McKaskey used small amounts, while Dickson reports the use of 85 c.c., or about 250,000 units. If a case of botulism occurs, careful search for the poisoned food should be made and all persons who have eaten it should be given good sized prophylactic doses of the serum. Gastric lavage, free catharsis, supportive measures and, in the subacute cases, feeding by the stomach tube are indicated.

2. Psychotherapy in Ordinary Practice.—W. A. Potts holds that in general practice cases suitable for psychotherapy, many of which cannot be treated in any other way, frequently occur. The general practitioner has a great advantage in that he is able to select both the case and the patient; he is not confronted with the difficulty of the patient being disheartened by the failure of other treatment. He also knows in advance the patient's previous history, habits, and temperament, and so can quickly pass on to treatment. On the other hand, the quickest and best results of psycho-therapy are usually obtained with patients one has never seen before, especially if treatment is started at the first interview. The ordinary practitioner may not have sufficient reputation in this kind of practice to produce the impression on a patient that a specialist can; he suffers from an additional handicap in that often he has not time either for a prolonged interview, or for a sufficient number of consecutive treatments. The cases which the writer describes never required long treatment; many of them were cured at one sitting. The necessity for careful diagnosis is emphasized. With psycho-therapy the greatest refinement of diagnosis is required—not merely a general idea of whether the condition is in the main functional or organic, but a decision often in regard to the nature of each symptom, because experience has shown that it is absurd to limit the use of this important branch of therapeutics to the so-called neuroses. Certainly it is valuable in them, but it is even more valuable in dealing with many of the symptoms of psychic origin associated with organic disease, such as continued vomiting in phthisis, and insomnia and chronic pain in many illnesses. Cases are cited in which psycho-therapy was employed in the treatment of neuroses, of paralysis agitans, in pregnancy and lactation, in neurasthenia, and for the investigation of criminal cases. The writer believes it will furnish the explanation of many illnesses and diseases, and is a powerful agent in relieving chronic pain, distress, and anxiety; it is also, in his opinion, an important factor in promoting efficiency and in strengthening character.

2. Chronic Intestinal Stasis in Children.—Godfrey Taunton states that chronic intestinal stasis is apt to be regarded as a condition affecting maturity because it is generally after this stage of life has been reached that patients present themselves for treatment, but only a few, if carefully questioned, fail to give a history which leads to the susupicion that their condition started in childhood or early infancy. Chronic intestinal stasis in children produces ill effects in several ways. In the first place, from autointoxication—the introduction of poisons into the blood stream through the intestinal mucous membrane affecting harmfully

all the tissues of the body. In the second place, it produces ill effects by bringing about a condition that leads frequently to infection of the sterile gall bladder and pancreas, and of the appendix, which cannot be claimed to be sterile. In the third place, it produces ill effects in the bowel itself. The portion of the intestine in which the stasis occurs is dilated, and from constant weight of its contents that part of its mesentery is lengthened, and a loop is formed which tends to gravitate toward the pelvis. Ulcerative processes, often tuberculous, are common, and by many cancer of the bowel is regarded as the end result of stasis. So great is the misery produced in later life that if, as a result of its study in children, the condition can in some cases be prevented, in some cured, and in others improved, a great advance will be made, and we shall see fewer of those chronic invalids—dyspeptic, neurasthenic, incapable of performing useful work or enjoying active pleasures, with a distaste for food and an abhorrence of sexual intercourse. The earlier the condition is recognized the easier it is to effect a cure, and in some cases in which an operation is called for it is one of less severity than in later years. In far the greater number of cases at an early age an operation is not necessary —other treatment will prevent the progress of stasis and ultimately overcome it. After discussing the types of chronic intestinal stasis, its various manifestations, its complications, and the diagnosis, the writer considers the treatment, dealing first with preventive measures and next with the treatment, by operation or otherwise, of the condition once it has appeared.

Le Bulletin Médical.

November 8, 1919, xxxiii, 49.

Glandular Insufficiency in Pediatrics.—Tixier mentions the great importance of this subject. Many severe infections of childhood incidentally damage the endocrine bodies. The resulting picture shows much polymorphism which is increased by the fact that a gland may be involved in very different degrees. In many cases therefore it is very difficult to name the particular syndrome. Thyroid deficiency of a notable degree is seen in the subject with congenital myxedema, the cretin and in so-called Brissaud infantilism which may also be called acquired myxedema. The younger the child when the condition appears the more pronounced the picture. The petty signs of thyroid insufficiency are of much interest. Some of these are a migranous type of headache or occipital neuralgia which is worse in the morning and interferes with school work; marked exhaustibility without great effort having been made; tendency to fall asleep after eating; pale and cold extremities; slight tendency to obesity, etc., etc. The author next mentions the addisonian syndrome which in the child nearly always means tuberculosis of the adrenals. A special syndrome accompanies the acute infectious diseases and has been often described. The abortive forms of hypoadrenia present apathy and an unconquerable sluggishness of mind and body, emaciation and slowing of growth and subnormal temperature, and are almost peculiar to boys. Other syndromes are in doubt and the senile dwarfism of Gilfort seems entirely inconsistent with the hirsutism of Apert. However, while the former has been encountered in atrophy of the adrenals, the latter has only been seen in tumors of the same. Pituitary insufficiency is not very common nor well defined in the child. Insufficiency of the gonads causes a form of infantilism in boys which is probably the same as eunuchoidism of authors while ovarian insufficiency causes also infantilism with slight inversion of the secondary sexual characters. Of pluriglandular syndromes must first be mentioned the adiposogenital dystrophy in which the hypophysis and testicle or ovary participate.

La Presse Médicale.

November 5, 1919, xxvii, 65.

Alimentation of Children.—Nobécourt states that the alimentation of the child above 3 years of age has been comparatively neglected. This neglect extends throughout the entire period of childhood or up to the time when the adult ration is consumed. This is termed neglect only in comparison with the extraordinary interest in the nutrition of the very young child, but the student will be well repaid by the same intensive study of the requirements of the older child. The limits placed on the problem in the present article are from 2½ to 15½ years of age. Since the growing child has a special requirement of tissue-food, the problem differs from that of the adult. While the dynamogenic requirement can be readily calculated from the factors of weight, sex and activity, the tissue-builders are neglected. These can well be ignored when food is plentiful and cheap, but in times of rationing must be carefully reckoned. There is a loss of heat radiated from the surface which should be borne in mind under calory requirements. The specific surface or amount which corresponds to a kilo of weight diminishes from the time of birth when it is 6.5 sq. dm. to 3.5 sq. dm. at the age of 15 and after. There is but little change from then on, for in the adult the specific surface is reckoned at 3 sq. dm. for a weight of 55 to 60 kilos. The number of calories radiated per specific surface is diversely computed. For the nursling a safe estimate is 15 per day. This holds good up to the weight of 30 kilos, and above that 14 per day per surface should hold good. We then have only to multiply the two figures—surface and calory number—to get the total radiation per kilogram-day. Then at each gain in weight we can calculate the increase in radiation. If a nursling gains one gram in weight he loses by radiation two more calories. These increments are known as growth calories. The work calories despite the great activity of the young child are comparatively few as the real output of energy is small in comparison with that of an adult engaged in an occupation. Hence all but a small fraction of the heat and energy food goes to maintain the animal heat. A child aged 5 years needs less than 1000 daily calories. The requirements at 15 are practically those of an adult whose occupation is not too active. Under protein requirement for growth and repair the author has but little to state although this appears to be the crux of the matter. The daily protein for a child of any age is made the same outright as that for the adult, or 100 grams, but the child uses more animal protein and less vegetable protein (sixty animal as compared to about fifty, and forty vegetable against fifty).

Le Bulletin Médical.

November 1, 1919, xxxiii, 48.

Treatment of Inoperable Cancer of the Tongue.—Belot states that radiation is the only treatment for this condition, for electrotherapeutics has not made good. In regard to the relative merits of radium and the *x*-rays, the former is the more satisfactory, according to the consensus of opinion, but the author dissents and finds what in theory should be the case that the action is essentially the same in either case. The recent improvements in *x*-ray technique give them a rank in part equal to that of radium for this locality. In fact, with the improvements mentioned, the rays are the more available remedy. Nevertheless radium retains certain advantages in an organ like the tongue, for the radium tube can often be inserted at the very seat of the mischief, when the rays are at a disadvantage. Or rather it might be best to state that the two methods can supplement each other, for radium can, so to speak, attack from within outward while the rays reverse this order. An important feature of the treatment is radiation of the glands, beginning with the submaxillary and anterior carotid and extending later to the lateral nodes of the neck. The deepest rays should be used through a 4 or 5 millimeter aluminum filter. At the same time tubes of radium are used within the mouth and also in very large ganglia. But while the immediate results may be brilliant it must be remembered that the treatment is essentially palliative, because it is impossible to reach all the cancerous tissue. Untoward results are due to defective technique, however, for the treatment properly given should never aggravate. In three cases cited by the author, one patient had a nodule on the tip of the tongue which had begun to ulcerate; while the submaxillary glands were enlarged. The first treatment was excision, as

the case was deemed operable. The microscope showed that in all probability the tumor could not have been completely removed and radiation followed. The patient has lived six years, and has had no relapse as yet. The second patient showed a diffuse cancer of the organ which was extremely painful. Both forms of radiation were used and the patient secured relief from pain and increased mobility of the organ, while the glands dwindled in size. The patient lived two years and died of an intercurrent pulmonary affection. In a third patient with inoperable recurrence the disease has been brought almost to a standstill. But such cases are the exception and are outweighed by numerous others, in which treatment has proved almost inert.

Correspondenz-Blatt für Schweizer Aerzte.

November 6, 1919, xlix, 45.

Acute Death in Heart Diseases.—Frey refers to sudden cessation of cardiac action and respiration, with death in a few seconds. It has been called "second" cardiac death. These deaths are not uncommon in patients with heart disease and during the last three years at one of the Kiel medical clinics there have been seventeen such. Eight occured in children with diphtheria. Three others occured in acute endocarditis with valvular lesions. Two occurred in mesoaortitis luetica with aortic insufficiency. Concerning the rationale of these cases we know but little. It might be said that the cardiac muscle gives out, becomes insufficient. But if this were the case there should be acute dilatation and venous stasis and neither is present in typical cases. Hering, who introduced the term "second" death believes that the cause is heart flutter, but the author does not concur. The electrocardiac proof cannot of course be forthcoming in such subjects as a matter of routine. The author, however, has taken electrocardiograms of the dying in 20 cases but never saw flutter, although he has observed extrasystole and hemisystole. Clinically he never saw heart flutter in "second" death. The synchronous stoppage of respiration should throw light on the subject, for this is not present in many forms of sudden death. In psychic shock we may see circulation and respiration arrested together and it has been seen in the mysterious deaths which follow falling in the water and also in chloroform deaths. The mechanism of "second" death is attributed to a shock action which affects simultaneously the centers of respiration and circulation. As a psychogenic motivation cannot be accused the author is forced to suggest a reflex mechanism originating in the heart itself. The reflex paths are naturally sensitized by the underlying disease of the heart.

La Médecine.

October, 1919, i, 1.

French Surgery, 1914-1918.—Mathieu states that French surgery during the great war exceeded all expectations. Owing to the fact that the internes in French hospitals are trained in operative surgery France possessed at the outbreak of the war thousands of potential operators from which the elite could be chosen for rapid mobilization. Each surgeon was the nucleus of a unit which comprised an assistant surgeon, anesthetist and two orderlies. The work of the surgeon was supplemented at the front by that of the radiographer, bacteriologist and chemist. Founded on laboratory data the first great step agreed upon was wide extirpation of infected foci, followed at the right moment by secondary suture. In certain cases immediate suture was found to be justifiable. This resource had to be practised at a very early moment and gave good results in joint and bone lesions, and wounds of the lungs and brain, where wide resection was contraindicated. As a tribute to radical methods gas gangrene and tetanus became increasingly uncommon. Naturally such a result was due largely to preventive serotherapy. The Paris Society of Surgery acted throughout as a clearing house of surgical practice and the numerous important subjects which came up for discussion included not only technics in the limited sense but organization and administration. We are now in position to appraise the value of military experiences for civil practice. Accidents which occur in the industries will benefit by the lessons in preparation of wounds of the extremities with immediate closure. The course of healing should be shortened, the functional result better than of old. In some cases of open fracture the bones will be sutured at once and the exposed joint cavities closed promptly. But there will be lessons in the opposite direction, wider exposure of deep structures when there have been penetrating wounds or when drainage is everything. Reconstructive and plastic work will have a great impetus with especial reference to grafts of all kinds. Valuable experience in the use of anesthetics of all kinds has been gained.

La Presse Médicale.

November 19, 1919, xxvii, 69.

Epilepsy and Anaphylaxis.—Pagniez and Lieutaud remark on the frequency of comitial attacks after gastrointestinal disturbance and the natural tendency to accuse special food articles. Well known to be of anaphylactic nature at times are urticaria, asthma and migraine, as shown by the nature of the cure. An epileptic boy of 18 with mentality of 13 or 14 was suspected of having a change in his blood picture before some of the attacks and hence blood counts were taken from time to time. Normally after a meal there was a slight upward change in the white cell count (digestive leucocytosis) and blood pressure; while on special occasions there was a sudden fall in the white count, the latter being reduced by as much as 2000 for a brief interval. The "clue" was a slight one, but the authors followed it up. In seeking for a food article which might figure in an anaphylaxis, chocolate was thought of; for on two occasions migrainous subjects had accused it of bringing on paroxysms. With a given meal the boy received 50 gms. chocolate, whereupon the white count made a sensational fall to 3600 from an initial 7000. Several hours after the count was taken an epileptic seizure followed. The authors then waited for another attack to come about spontaneously and two days after this event the boy was again given chocolate. The leucocyte count showed no change and no seizure developed. A few days later the experiment with chocolate was repeated in a little larger amount. Once more the white count suddenly fell—from 11,500 to 5400. The blood pressure, unchanged in the first experiment, also fell considerably and that night patient had three seizures. A control patient, non-epileptic, ingested chocolate without any disturbance of the white count. This case is only an entering wedge for further study, but it seems assured that a relation subsists between certain food articles, a hemoclastic crisis and an epileptic seizure in a predisposed subject.

Folk Syphilis in Denmark.—Ehlers writes entertainingly of this subject, making a sharp distinction between folk syphilis and the venereal form. The former was well known in the XVIII century and resembled the "radesyge" of Norway, especially in its destruction of the nasal skeleton. The victims were either infected extragenitally or had their disease overlooked. While the socalled "Juske" syphiloid was not known before the close of the XVIII century there are several accounts of local epidemics of folk syphilis at earlier periods, including one at Jutland itself, where the "Juske" syphiloid later originated.—*Norsk Magazin for Laegevidenskaben.*

Specific Treatment of Vincent's Angina.—Capitan injects colloidal arsenic into the buttocks, using Frouin's technique. In 24 hours we find the buccal cavity nearly sterile of these germs, even in the absence of local treatment. In another 24 hours not a spirochete or fusiform bacillus is to be found. Only in very severe cases was a second injection necessary. The treatment is absolutely specific.—*Le Progès Médical.*

Pantoponism.—As could have been anticipated the introduction of this proprietary has led to numerous cases of habit formation which practically merge with morphinism. The prevalence of the habit will vary inversely with the strictness of enforcement of anti-narcotic laws and with the existence of restrictive laws. —*Office International d'Hygiene Publique.*

Book Reviews.

TRANSACTIONS OF THE FORTIETH ANNUAL MEETING OF THE AMERICAN LARYNGOLOGICAL ASSOCIATION, held at Atlantic City, N. J., May 27, 28, and 29, 1918. Together with the Record of the Association in the Great War. Published by the Association, under the Direction of the Acting Secretary, Dr. David Bryson Delavan.

This volume, which records the Jubilee Celebration of one of the oldest, ablest, and most distinguished of the organizations representing the specialties in this country, is a valuable addition to the literature of the World War period, for it contains the inspiring war record of the association. The total membership of the organization, as we are told in the Foreword, is 81. Of these not more than 48 were eligible for active service; of this number 38 were in uniform. The list includes 1 brigadier-general, 4 colonels, 6 lieutenant-colonels, 15 majors, 5 captains, 3 lieutenants, and 4 contract surgeons. The volume includes the honor roll of those who served overseas and at home, whether in the Medical Reserve Corps, the Volunteer Medical Service Corps, or miscellaneous service, and contains 3 portrait groups and 15 portraits. The Report of the Activities of the Committee on Oto-Laryngology of the Council of National Defense, by Col. Charles W. Richardson of Washington, D. C., and an Informal Report on Oto-Laryngology in the First Year of the War, by Col. Harris P. Mosher of Boston, form valuable records of the activities of otolaryngologists who saw service during the war.

The history of laryngology is reviewed in a paper on the early days of laryngology, by the honorary president, Dr. J. Da Silva Solis-Cohen of Philadelphia, reminiscent sketches by Dr. Henry K. Oliver of Boston, Dr. Samuel Johnston of Baltimore, a letter from the late Dr. E. Fletcher Ingals of Chicago, and a paper on the influence of New York upon the development of laryngology, by Dr. D. Bryson Delavan of New York. A unique feature of the historical part of the volume is the reproduction of the report of the proceedings of the meeting in 1878, at which the association was organized.

The remainder of the volume contains the report of the regular scientific proceedings, an account of the annual dinner, and the record of the executive sessions, together with the list of members, 44 cuts and 2 vignettes, and the table of contents.

PSYCHOSES OF THE WAR, including Neurasthenia and Shell Shock. By H. C. MARR, Lt.-Col. R.A.M.C. (Temp.), Director of Medicine; Fellow of the Royal Faculty of Physicians and Surgeons, Glasgow; Neurological Consultant to the Scottish Command; H. M. Commissioner of Control for Scotland; Formerly Specialist in Nervous Diseases to the Troops in Malta (1915-1916); Physician Superintendent of Glasgow District Mental Hospital, Woodilee, Lenzie; Referee, Under the Workmen's Compensation Act, for Dumbartonshire; and Mackintosh Lecturer in Psychological Medicine, St. Mungo's College, Glasgow. London: Henry Frowde, and Hodder & Stoughton. New York: Oxford University Press, American Branch, 1919.

IN the first chapter, or Introduction to this book, the author deals with the borderland of mental disease; normal obsession, abnormal obsession, imperative ideas; the seat of mind and mental phenomena; means of observation of mental phenomena, with a table giving the classification of mental affections; simulation of mental affections; malingering, feigned insanity. The author then proceeds, in chapter two, with the discussion of the psychopathies, under which he considers hereditary and constitutional psychoses—neurasthenia (shell shock), which he classifies as simple, hysterical, and organic.

The third chapter is devoted to psychasthenia, which Dr. Marr considers to be the counterpart of neurasthenia, in the latter the nervous weakness being most prominent, while in the former the mental phenomena attract most attention. Psychasthenia, in other words, is a mental state superimposed on one of the forms of neurasthenia. In the fourth and fifth chapters are considered, respectively, mental deficiency (infantile), and mental enfeeblement (adolescent). In the sixth chapter the author deals with toxic psychoses or confusional insanities, the essential features of the toxic mental conditions being the confusional insanities. In the seventh and last chapter are considered organic psychoses (cerebropathies), under which are included cerebral syphilis; metasyphilitic affections, such as general paralysis and locomotor ataxia; head traumatisms; and insanities associated with arteriosclerosis, senile decay, and cerebral tumor. The general considerations herein outlined are the results of observations, begun shortly after the beginning of the war, of some 18,000 officers and men. Relatively little space is devoted by the author to the treatment of the several conditions discussed in the volume, with the single exception perhaps of the general treatment of neurasthenia.

AN OUTLINE OF GENITO-URINARY SURGERY. By GEORGE GILBERT SMITH, M.D., F.A.C.S. Genito-Urinary Surgeon to Out-Patients, Massachusetts General Hospital; Assistant Visiting Surgeon, Collis P. Huntington Memorial Hospital; Captain Medical Corps, U. S. A.; Member of the American Association of Genito-Urinary Surgeons and of the American Urological Association. Authority to publish granted by the Surgeon-General, U. S. A. Illustrations by H. F. Aitken. Philadelphia and London: W. B. Saunders Company, 1919.

THIS little book has been written with the idea of presenting to students and general practitioners the important points in the symptomatology and pathology of genito-urinary diseases. It fulfils this promise and justifies its reason for existence. The author's style is clear, direct and simple, and his book adequately bridges that hiatus between the quiz compend and the pretentious text-books on urology.

STERILITY IN WOMEN. By ARTHUR E. GILES, M.D., B. Sc. (Lond.), M.B., Ch.B. (Vict.), F.R.C.S. (Edin.), M.R.C.P. (Lond.). Captain R.A.M.C. (Temp.). Senior Surgeon to the Chelsea Hospital for Women, Gynecologist to the Prince of Wales General Hospital, Tottenham. With eleven illustrations. London: Henry Frowde, and Hodder and Stoughton; New York: Oxford University Press, American Branch, 1919.

THIS is a good book on an important subject. The author is well known as joint-author with Sir John Bland Sutton of a book on Diseases of Women which has gone through several editions, and as the author of a useful little volume on Gynecological Diagnosis. The present work is somewhat on the lines of the Gynecological Diagnosis. The author begins by disclaiming any idea of being considered a specialist on the subject; but his book is based on a very large experience, and his statistics and inferences are based on some 4,500 cases. The fact that the author does not claim to be a "specialist" adds to the value of his book, in that he does not take the narrow view of the subject which so often characterizes the work of the mere specialist. There is an introductory chapter on man's share of responsibility for childless marriages, and the author gives the figures of different authors placing this responsibility anywhere between 10 per cent and 90 per cent. The next chapter is on the proportion of unproductive marriages. Then follow two chapters on the causes of sterility; in one, the classification of these causes is on a pathological basis, in the other the subject is viewed from the clinical standpoint.

The interesting subject of functional sterility is next discussed. This is followed by several chapters on primary sterility, which is regarded as of two kinds, congenital and acquired. Secondary sterility is next considered, and then the author discusses the diagnosis of the causes of sterility. Two chapters follow on the prognosis and treatment. The volume closes with a valuable bibliography on sterility, arranged chronologically and including approximately 250 titles, and ranging from 1609 to 1913. The work includes the labors of others as well as the author's own experience, and the whole is welded together in a masterly manner. The general practitioner will find this a valuable volume on a subject which is always of interest and never more so than at the present time.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held October 9, 1919.

DR. MURRAY H. BASS IN THE CHAIR.

Chronic Arthritis with Subcutaneous Nodules and Enlargement of Lymph Tubes and Spleen.—Dr. MAY WILSON presented this patient, a girl of 8 years of age, with a tuberculous family history, and giving a positive von Pirquet reaction. The child had a rheumatic history. She developed an arthritis of the right knee-joint at the age of 5½ years followed by repeated involvement of joints in the following order: knees, wrists, spine, ankles, carpus, and phalanges, with periarticular thickening, stiffness, no redness and little pain in the joints. An enlargement of the lymph glands was associated with the arthritis, the course of their involvement following closely that of the joints. There was early and persistent enlargement of the liver and later enlargement of the spleen. Subcutaneous rheumatic nodules had developed along the tendons and bony prominences. Since the child had been under observation enlargement of the heart had developed with pericarditis and possibly endocarditis. The onset of the condition was acute. It had lasted two and one-half years. Thus far no focus of infection had been found. The case presented a problem in differential diagnosis. Was it a case of intractable rheumatism, characterized by swelling of the joints of a subacute nature, fibrous nodules near the joints, with lymphatic gland involvement, and a rheumatic history? Such a form of rheumatism was rare in this country. Or was it an early case of Still's disease (infectious arthritis), since in addition to the arthritis the glands and spleen were involved? Again, might it be a case of tuberculous rheumatism as described by Poncet, who cited a similar case in which there was a tuberculous family history and a positive von Pirquet. Finally, could it be a case of arthritis deformans occurring in childhood? The blood culture was negative, during exacerbations. The urine showed albumin ½ plus. An *x*-ray of the heart showed slight hypertrophy of the right ventricle. There was no evidence of bone or cartilage destruction.

Dr. OSCAR M. SCHLOSS said he had had the opportunity of seeing the case and probably the diagnosis was subacute rheumatism with tremendous development of rheumatic nodules. As to the question of Still's disease, some of these cases were very slow in developing and had recurrent attacks and intervals of remission such as this child's history showed. However, the evidence at the present time was in favor of this being a rheumatic case with fibrous rheumatic nodules.

Dr. HERMAN SCHWARZ said that in rheumatic fever with heart complications, where the patient had had a high temperature and was very sick, one usually found rheumatic nodules if he followed Dr. Brenneman's advice and looked for them. If one removed a nodule, examined it and found Aschoff bodies, he could be sure he was dealing with a case of rheumatism. If the nodule was too old Aschoff bodies would not be found. He agreed with Dr. Schloss that this case was one of subacute rheumatism since the child had had the trouble for several years and there was not much deformity. One rarely saw the kind of a hand this child presented at such an early age, and this made him think that possibly Still's disease should be taken into consideration.

Dr. GODFREY R. PISEK said that the child fell in with the description given by Still, but even if the case were accepted as one of Still's disease we would be just as far away from knowing the etiology as though we called the case one of chronic rheumatism. The fact that the child had had various arthritides, the character of the temperature chart, and the splenic enlargement made him feel that it should be put under the classification designated as Still's disease.

Dr. HENRY BERG expressed the opinion that cases of Still's disease seemed to be much more numerous formerly than at the present time, and he wondered whether there were really fewer cases or whether it was because he did not see as many dispensary cases as some years ago. The fact that the nodules in the case resembled those of arthritis, that the joints were stiff, that enlargements had not occurred unless there was fever, that there were recurrences, and that there was enlargement of the liver, spleen, and lymph nodes, together with a tuberculous history, would make one think immediately of Still's disease. Though very little was known of the pathogenicity of this disease it was certain that the symptoms presented in this case came very close to the picture of Still's disease.

Dr. L. E. LA FETRA said the unusual feature in this case was the enlargement of the lymph nodes; otherwise it would be easy to classify the case as one of subacute rheumatism. Among hundreds of cases of rheumatic arthritis it was rare to find a case with enlargement of the lymph nodes. It was quite possible that the child, as suggested by Dr. Schloss, was on the way to develop Still's disease.

Dr. SIDNEY V. HAAS called attention to the fact that it was not so very long ago that the finding of these fibrous nodules was considered as indicating a bad prognosis. This opinion had undergone a change. This case would seem to substantiate this attitude, for although the child was rather sick the prognosis for an early death did not exist. The case illustrated very well the confusion which existed in the literature of rheumatism. Still's disease was in reality only a chronic sepsis. This child represented the clinical picture of three diseases: (1) Lymphadenitis, (2) rheumatism, (3) Still's disease, due to one etiological factor, chronic sepsis.

Dr. ROGER H. DENNETT stated that Dr. Haas had described the situation exactly. The fact of importance was that the child was suffering from a chronic infection. It might be from the middle ear, a sinus, the teeth, or what not. He felt that on this point the future textbooks would be simplified, not being satisfied with describing various pictures of each type of infection and giving them a name, but would say "this is one of the many manifestations of blood infection coming from focal infection."

Dr. WILSON, in closing, said that they were expecting to have an examination of a nodule, but they were waiting until they could get a fresh one, as Poynton and Paine in "Researches and Rheumatism" state that fresh nodules showed the characteristic morphology and could be stained for organisms. Dr. Koplik and Poynton and Paine had cited similar cases. Poynton said he could not classify the disease, but thought it took a middle position between chronic rheumatic arthritis and Still's disease. The teeth and sinuses had been examined and found negative.

Hyperpigmented as Contradistinguished from Hemorrhagic Measles.—Dr. HENRY W. BERG presented this paper, in which he stated that true hemorrhagic measles was an extremely fatal disease, being considered by many experts in communicable diseases as uniformly fatal. Others believed that some exceptional cases might recover. Many years ago he had been impressed with the fact that the cases of measles with a hemorrhagic skin eruption that recovered were not clinically very sick patients. The cases of hemorrhagic skin eruption that showed the manifestations of severe illness and finally died were from their beginning entirely different in type from those that recovered. The temperature was very high or subnormal, the pulse very rapid, there were hemorrhages from the nose, eyes, and other mucous membranes, including those of the stomach and bowels; there was hematuria, and there were toxic cerebral symptoms. It was a curious fact that in these malignant cases most of the eruption was not hemorrhagic, but disappeared during pressure as did the eruption of ordinary measles. There were cases in which the eruption was a perfectly normal one accompanied by a lesser degree of hemorrhages into the mucous membranes and a lesser degree of cerebral and general toxemia. Yet even in these cases it was proper to predict a fatal result with the preceding occurrence of a bronchopneumonia, nephritis, or other serious complication, for these were also cases of nonfulminating yet true hemorrhagic measles. The cases to which he particularly called attention were those in which the eruption as a whole was hemorrhagic, that was to say, it did not disappear during pressure, but on the contrary became more brilliant during pressure.

This was true not only in spots, but over whole extremities and large areas of eruption, or even over the whole surface of the skin eruption. The eruption looked as though it were painted with fixed dyes underneath the epidermis. It was slightly elevated and was apt to be confluent. The more the skin was compressed the more brilliant the eruption became. This type he had called "pseudo-hemorrhagic" or "hyperpigmented" measles. The hyperpigmented character of the eruption was rarely marked on the first day, but generally observed on the second or third day by the failure to pale and disappear on pressure as happened to ordinary measles. The hyperpigmented eruption was much more brilliantly red than ordinary measles; the papules were more elevated, and the macular portion of the eruption was almost as red as the papule. The eruption endured in its full brilliant color up to the seventh or eighth day before it began to fade, during all of which time it retained its characteristic of not fading on pressure. In hyperpigmented measles the desquamative stage was delayed, and when it began the furfur was coarser with larger scales than those of ordinary measles. There were cases in which the whole eruption was of the hyperpigmented type, while in others only a portion of the eruption was hyperpigmented, the rest of the body being covered with ordinary measles. The exanthematic portion of the eruption, particularly on the soft palate, was more marked and clearly defined than in an ordinary case of measles. In these cases, in contradistinction to true hemorrhagic measles, there were no petechial or purpuric spots and no extravasations of blood, and no hemorrhages from the nares, throat, mouth, conjunctiva, stomach, or bowels, etc., as in hemorrhagic measles. Koplik spots were present about as early and to the same extent in hyperpigmented as in normal measles. The essential pulse and temperature curves characteristic of measles were present in cases of hyperpigmented measles but were as a rule on a higher scale than in cases of ordinary measles. The hyperpigmented cases never presented a subnormal temperature curve. The fastigium stage of the temperature curve in the hyperpigmented cases was fully two or even three days longer than in ordinary measles. The resolution of the temperature curve by crisis, so characteristic of normal measles, occurred in hyperpigmented cases, too, but generally two or more days later. Myocarditis and arrhythmias were not present in uncomplicated cases of hyperpigmented measles. Bronchopneumonia occurred as a complication, but not as frequently as in ordinary measles. The prognosis for recovery of such a complicating bronchopneumonia was very much better in the hyperpigmented cases than in ordinary cases of measles. A point to be particularly stressed was that the prognosis of hyperpigmented measles was an extremely favorable one.

Dr. E. M. GIDDINGS stated that he had observed some 2,000 cases of measles and had found among them 60 cases of hemorrhagic measles and one case only of hemorrhagic measles in the sense of being the malignant form of hemorrhagic measles, that was with hemorrhages from the various mucous membranes. Among these there were 17 patients with bronchopneumonia, of whom 9 died. Twenty-four cases had otitis media, which was a little less than the average incidence of this complication among measles cases. The course of the disease when of the hyperpigmented type was usually milder as to complications than that of ordinary measles. The temperature curve in hyperpigmented measles was as Dr. Berg had described it. The fever usually lasted three or four days longer than in the ordinary type of measles, usually coming down on the seventh or eighth day.

Dr. L. E. LA FETRA said all were familiar with this type of benign hemorrhagic measles and the thing that struck one when he first saw such cases was the surprisingly good outcome as compared with that of true hemorrhagic or malignant measles. With reference to designating this type of measles by the term "hyperpigmented," Dr. Berg had criticised his own caption when he said that the term hyperpigmented described only the latter part of the disease. Why, then, give the disease that name when one wanted to know something about the disease when he made the diagnosis? Dr. Berg had used the term hyperpigmented to mean bright red and also to mean dark brown. Would not the use of some term such as benign hemorrhagic or mild hemorrhagic be better?

Dr. HERMAN SCHWARZ expressed the opinion that the terms malignant and nonmalignant, with or without hemorrhages, would serve as a simple index to distinguish these different types of measles.

Dr. MURRAY H. BASS said he was particularly interested in the statement that these cases of hyperpigmented measles should be differentiated from the ordinary ones on account of the fact that the complications ran a more favorable course than in the other type. It had seemed to him that the difference was due to a difference in the skin of the patient and to the fact that the blood capillaries of such patients broke easier than those of others; or he thought that hemorrhagic measles might be complicated with some other condition which rendered the skin capillaries of the patient particularly susceptible, so that they broke easily. The fact that these cases ran a longer course might be due to the absorption of the extravasated blood. If these cases of hyperpigmented measles ran a milder course as regards complications it was perfectly proper to think that we were dealing with a different type of measles.

Dr. BERG, in closing, said he was glad to see that Dr. Giddings brought out the point that there was a large number of cases of hyperpigmented measles. However, the cases were not simple hyperpigmented measles if the patients died. The important points in reference to hyperpigmented measles were the longer course of the disease, the fact that the patients did not have severe constitutional symptoms, and that they had hemorrhagic essential measles lesions. These cases had been called hemorrhagic measles, but they were not hemorrhagic measles. Hemorrhagic measles was a fatal disease, so that from the prognostic standpoint one should not make a diagnosis of hemorrhagic measles when the case was one of hyperpigmented measles. The term pseudohemorrhagic would not do because there was hemorrhage so far as the lesion itself was concerned, but one would not find other hemorrhagic spots or petechiæ; compressing the lesion did not cause these measles spots to disappear or fade. If one found no other hemorrhages except the hemorrhagic measles lesion the condition was hyperpigmented measles, and one was at liberty to make a perfectly good prognosis in the noncomplicated cases. There were two kinds of true hemorrhagic measles: (1) The foudroyant, in which the patients died promptly, and (2) a type in which there were severe complications and the patient died after two or three weeks. The hyperpigmented type was an absolute entity and one could make the diagnosis on the eruption and on the fact there were no constitutional symptoms and no toxemia, and the patients never died but invariably got well. Even when complicated, hyperpigmented measles had a better prognosis than simple measles when complicated. The fact to be impressed was that these cases must not be classified as hemorrhagic, but must be called by some other name, it did not make any difference whether it was hyperpigmented or a name that came nearer the truth. If a more appropriate name could be found he was willing to have it adopted. If those members of the section who had charge of large children's contagious disease services would watch their cases of measles for a winter or two they would find a certain number of cases which they would designate as hyperpigmented, and when there was a discussion on the next paper on this subject they would be able to talk about hyperpigmented measles as an absolute entity.

Thick Cereal Feeding in Malnutrition in Infancy.—Dr. HAROLD RUCKMAN MIXSELL read this paper. He stated that his attention was first called to thick cereal feeding in infancy through an article by Dr. L. W. Sauer of Chicago on thick cereal feedings in cases of pyloric stenosis and pylorospasm. He later had the opportunity of taking care of one of Dr. Sauer's cases and had noted the remarkable results obtained in this condition. It occurred to him that it would be an excellent idea to try out the thick farina feedings in cases of marasmus. Accordingly four cases in the Nursery and Child's Hospital and 12 cases in private practice were selected, the ages running from four

weeks to six months. The hospital cases were babies who had approached hospitalization, were physically not abnormal, and had all been tried on various formulæ in the endeavor to make them gain. The cases in private practice were the same type. The stock formula on which these babies were started was approximately one tablespoonful of farina to seven ounces of a one per cent. milk. Skimmed milk was used on account of its comparatively higher protein and salt content. To the entire formula about three per cent. of cane sugar was added. Later dextrimaltose was added. All of this was cooked for at least thirty minutes, or until the cereal was so tenacious that it would barely fall off an inverted spoon. It was found that if the cereal was not well cooked the baby might get up a diarrhea from the high starch content. In four of the cases rice flour was used. This had the advantage of being more soluble and had better protected colloids than farina. The pyloric reflexes, therefore, were better inhibited and were not as active. Two cases were described in detail as typical of the other 14. In every case there was a decided change for the better physically and a decided gain in weight. A striking point about these feedings was the high caloric intake which these babies would handle, in many cases it being 300 calories or more over their requirements. In regard to the length of time one could keep a child on thick cereals, there was no fixed rule. In one of the writer's cases it was persisted in for eight months with good success. Naturally, other articles of diet were added from time to time, the green vegetables and fruit juices in particular being used. It seemed best, however, to make a change back to a milk formula at the end of about two months, dry milk being used in the majority of cases. In order to supply the water deficiency in these babies there was ordered water in amounts up to six ounces three times a day. The urine in every one of these cases was found normal, there was no loss of weight, or edema, or evidence of water retention. By the thick cereal feeding there was increased sugar tolerance with no disturbance of sugar or starch metabolism. In closing the writer said, in view of this series of tests, he felt that although we did not have a cure-all for all difficult feeding cases, the results justified its thorough trial.

Dr. L. E. La Fetra congratulated Dr. Mixsell on his good results with the thick cereal feeding. He felt that these favorable results were in a measure due to the use of protein in the form of skimmed milk boiled with the cereal. They had used the cereal boiled only in water, and while in that way they had been able to prevent vomiting, they had lost sight of the protein requirements.

Dr. Herman Schwarz said that if from no other standpoint it was interesting and instructive that infants of two, three, and four weeks of age could be fed with thick cereals.

Dr. Charles Hendee Smith said that it had been known for some time that cereal gruels were a last resort in the feeding of vomiting babies. There were many ways in which these gruels could be made up. As he remembered Dr. Porter's paper, rice flour was used and, as rice flour did not thicken as much as some other cereals, it was necessary to use twelve or fourteen tablespoonfuls to make up 30 ounces. It was the speaker's practice to use cream of wheat, which took only five level tablespoonfuls to make 30 ounces, which was practically the same proportion as Dr. Mixsell's mixture, one tablespoonful to six ounces. Dr. Smith said he ordered the cereal cooked in a pint or less of water for one hour and then the milk in any amount necessary to be added and brought to a boil or not, as desired. The result was a solid cereal when cool. In this method whole or skimmed milk might be used and any form of sugar might be added. The results with vomiting babies were regularly excellent. Dr. Mixsell's paper suggested a valuable extension of thick cereal feeding to other difficult feeding cases.

Dr. Sidney V. Haas said it was interesting to know that one could get good results from thick cereal feeding and it gave a possible explanation of the good results obtained with malt soup. In both of these types of feeding there was a large quantity of carbohydrate. Dr. Mixsell had called attention to one point that was likely to be lost sight of, and that was the character of the colloids. The colloids were a factor of importance and one that was much neglected.

Dr. Henry W. Berg said he was impressed by the unimportance of the disturbance that might be caused by cereal feeding, but he felt that the results of feeding with atropine might be very important. He thought the feeding of food should be separated from the feeding of drugs, so that one would know just what the child was absorbing. If it became a habit to feed atropine in the food of sick infants there might be a higher death rate notwithstanding perfect feeding. In this food Dr. Mixsell gave all the chemical elements the child needed and he obtained good results. The feeding of thick, almost gelatinous food, prevented the slight tendency to vomit mechanically, and the child would retain such foods while fluids would be vomited. He had wondered, as had one of the other speakers, how many other children would have done as well as these children cited. He had known instances in which all kinds of scientific methods of feeding had been employed and failed, and then someone would induce the mother to try a patent food and the child would do well. There were a great many things we did not know about the patient and the way in which various foods affected various types of patients. The method of feeding which Dr. Mixsell had described was suggested only as an additional resort in cases of difficult feeding, and it would do good in some cases and do badly in other types of cases.

Dr. Mixsell said that Dr. Berg had expressed just what he felt by his last remark; this was simply one method of feeding that might be employed in difficult cases. He did not think it a cure-all by any means. In using rice one had to use twice as much as of other cereals. Feeding methods seemed to run in cycles and this was a modification of the pap feeding used in the sixteenth and seventeenth centuries. It was not a new method, but it might be used with advantage in a good many cases.

Intestinal Toxemia in Infancy; A Suggested Explanation.—Dr. Marshall C. Pease read this paper, in which he stated that it had long been recognized that the number of bacteria in the feces was much greater than the number of colonies that developed on plates. This discrepancy had been in part at least explained by improved methods of culture so that many of the Gram-positive spore-bearing anaerobes had been identified. A few of the more easily grown anaerobes had been isolated, but for the most part the field of research had yielded few results or had been neglected, so that but few identifications had been made. The *B. welchii*, the *B. sporogenes*, and the *B. putrificus* had been frequently found, as they were easily grown and recognized. There were two reasons for the neglect of the study of the anaerobes. In the first place it was the least developed field of bacteriology, the methods were cumbersome and difficult of application, the organisms for the most part were unclassified, and there was no literature in all medicine so unsatisfactory as that which had to do with this subject. In the second place the so-called putrefactive organisms had not been supposed to have a poisonous action, and it was taken for granted that their harmful effects resulted from the breaking down of the proteins rather than from any inherent quality that existed in the bacteria themselves. The easy acceptance of a tradition was no longer possible when we considered that we were dealing with a group of bacteria that were capable of elaborating toxins and could be shown to produce many and severe symptoms. Without a doubt it was these toxins that furnished the hitherto unknown toxic agent of those cases that had been designated as gastrointestinal toxemia of unknown origin occurring in children. It was now possible to indicate a source from which such toxins might be derived and to prove that they were capable of causing either mild or the severest possible degree of toxemia. These toxins were derived from a group of anaerobes that were commonly found in the intestinal tract of both infants and adults. They had been classified in the order of their pathogenicity and with an indication of their main action as regards the sugars and proteins into three groups. Group I was capable of elaborating a high titer toxin and included the *Vibrion septique*, *B. edematiens*, and *B. perfringens*, all of which had a saccharolytic action, while

the second and third had also a proteolytic action. Group II included organisms having a low titer toxin, as *B. fallax*, which had a saccharolytic action, and *B. sporogenes* and *B. aerofœtidus*, which had a proteolytic action. Group III included organisms which, so far as was known, never produced toxins and were chiefly of importance because of their association with the organisms which did produce toxins and their influence in heightening the toxicity of the toxin producing organisms. In this group were included *B. putrificus*, *B. tertius*, which had a proteolytic action, and *B. fermentans*, which had a saccharolytic action. The organisms of the first group showed great variability in their ability to produce toxins which they produced in high titer and in quantities in a medium rich in proteins and having an alkaline reaction. The putrefactive organisms derived their importance chiefly from the fact that they tended to keep the medium of an alkaline reaction and break down the proteins into their simpler compounds which might be more easily attacked by the pathogenic saccharolytic organisms. The symptoms developed by these toxins were dependent not alone upon the kind and titer of the toxin, but also to a measurable degree upon the size of the dose, namely, the number of organisms, conditions that favored the elaboration of a toxin, and the rapidity of the absorption. The writer discussed these conditions and the possibility of producing an antitoxin that should be effective against these toxins, and concluded that such an antitoxin was not yet on a satisfactory basis for practical purposes. However, such toxins could be experimentally produced, but had a low titer owing to their inability to obtain a sufficiently strong toxin. The variety of organisms against which protection must be furnished was another difficulty which at present seemed almost insurmountable. In this discussion only the more obvious toxic disturbances were considered. It was probable that many other conditions that had a milder and more chronic course would be found to have their real basis in these toxins—toxins that had a low titer and were slowly absorbed. As some of the toxins at least caused hemolysis, it might be that the severe unexplained secondary anemia loosely ascribed to faulty conditions in the gastrointestinal tract might find their real cause in these toxic agents.

Dr. GODFREY R. PISEK said they were very fortunate in that Dr. Pease, while engaged in army work in France with the gas bacillus, had thought of this subject from the pediatric standpoint and applied the principles and findings to infants and children. He had reopened an untrodden field. How unsatisfactory had been the subject matter dealing with the intestinal flora was shown in a study of the literature. If the doctor could offer a good explanation of these bacterial activities with their elaborated toxins, whether along etiological lines or along the lines of treatment, the work would be worth while. What he had told them offered an explanation of certain disturbances caused by high protein feeding. If high proteins were fed there might occur alkaline putrefactive stools with production of powerful toxins, and in making a diagnosis one should have that fact in mind. He also explained why high acidity occurred with high carbohydrate feeding. If now they could come to some practical means of deciding when they should adhere to carbohydrates in feeding these cases and when to emphasize the protein, they would have gained a great deal. A fact that struck one in doing autopsies on children dying of intestinal toxemia, so-called, was that only fatty infiltration was found in the organs and nothing gross or microscopical was to be seen to explain the cause of disorders and the production of death. If Dr. Pease had done nothing more than to stimulate research along the lines of intestinal flora and their toxin production he had done his share. The rôle of the anaerobes in this regard should prove illuminating.

Dr. ROGER H. DENNETT said this was pioneer work. They all felt that they needed some help in differentiating the various types of intestinal infections, which at the present time was more or less guesswork. He felt that this work would do a great deal of good if they would follow it out.

Dr. OSCAR M. SCHLOSS said that in these cases of intestinal intoxication in infants there was a diminished volume flow of blood due to the great loss of fluid through watery stools, and in some cases there were pronounced circulatory symptoms, even though the volume of blood was sufficient, to be accounted for as symptoms of acidosis and to be regarded as due to diminished secretion of urine, the result of suboxidation. If there was a diminished oxidation there was a diminished volume flow of blood and a marked acidosis ensued. The treatment was to give water intravenously, subcutaneously, or intraperitoneally, in order to bring the blood volume to normal. A ten, fifteen, or twenty per cent. sugar solution might be given. A saline solution should first be given and then this should be followed by a dextrin solution. Dr. Marriott had used gum acacia solution with excellent results. A point brought out by Dr. Pease which was very suggestive was whether the toxin formed in the intestinal tract was the cause of the symptoms or whether it was the loss of water that produced the symptoms. The first symptoms might be due entirely to water loss. On the other hand it was possible that the toxins were responsible for both the diarrhea and these symptoms. This was the question that should be definitely answered.

Dr. HERMAN SCHWARZ said that some ten or twelve years ago he thought he could divide the bacteria that caused some diarrhea into (1) the proteolytic, spore-bearing, gelatin-liquefying bacteria, often anaerobic, and (2) those which were of the ordinary pathogenic variety. In the course of the work he found more exceptions than cases which followed the rule, so that he finally gave it up. Anaerobic culture methods were not so well developed at that time, so that perhaps they might get a little further today. It would have to be very definitely proven that the toxins produced by the anaerobic bacteria actually were produced in the body and caused these symptoms. It brought them again to the old discussion whether the poisons that caused these conditions were secondary to bacterial activity or just pure chemical processes.

Dr. PEASE, in closing, said he did not present these things as actually proven, but he presented a series of organisms which did form toxins and were capable of producing a general toxemia which was exactly as he had pictured it. Dr. Schloss in his discussion had brought out the mechanism of these cases. If one took, for instance, acidosis, the symptoms were brought about by the mechanism described, but why the acidosis and why the disturbance in circulation? In many cases of toxemia there was no diarrhea. In such cases he felt sure the cause was in the nature of a toxin, and these toxins given to animals experimentally were capable of producing every symptom that a case of toxemia showed. The men who undertook to work out these organisms did not enter upon an easy road. He knew nothing so difficult as the isolation of these organisms in pure culture. There might be six or seven anaerobes that started as a mixed culture and then the problem presented enormous difficulties. For instance, one might take a culture of *B. edematiens* and run it through eight or nine cultures, always getting this organism. and then the *B. fermentans* might appear. This was because these were spore-bearing organisms and the spores had been carried along through the previous cultures.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held October 26, 1919.

DR. SOLOMON WIENER IN THE CHAIR.

Unruptured Tubal Pregnancy—Seventh Week.—Dr. HERBERT C. CHASE reported this case. He stated that his reason for calling attention to this case was not because of the rarity of the condition or of any difficulty in diagnosis, or because it was in any way atypical. On the contrary, it was so typical in every way that it served to bring out the points with reference to the diagnosis of unruptured tubal pregnancy. He had been amazed to find that although unruptured tubal pregnancy occurred 29 times in 309 cases of ectopic gestation recently analyzed by Dr. Farrar at the Woman's Hospital, the condition was diagnosed correctly before

operation in only a few cases. This patient was 24 years of age and previously healthy. She began to menstruate at the age of 14 years. Menstruation was regular, at 21-day intervals, lasting four days. Her periods were always associated with cramps and backache. She had never been pregnant before. Her menstrual period in July came at its normal time and lasted until the 21st with the usual cramps and backache. No menstrual period appeared in August. On September 2 she began to flow slightly. On the fourth day of the flow sharp pains began to be felt in the lower quadrant. The patient came to his office in a cab. She seemed to be suffering intensely. She was pale, blanched, and in a cold sweat. Her temperature was 98° F.; pulse 92. Physical examination showed considerable bleeding, the uterus retroverted and slightly enlarged, and a small soft mass palpable in the left tube. The breasts were engorged and tender. She was sent directly to the Woman's Hospital with the diagnosis of unruptured ectopic pregnancy. At operation a curettage was first performed and considerable tissue (false decidua) removed. Examination under ether gave results the same as shown at the previous examination. The abdomen was opened by a transverse incision. A small amount of blood was found in the abdominal cavity, and a small amount of blood was oozing from the fimbriated end of the left tube. An unruptured tubal pregnancy, the size of a lemon, was found in the middle third of the tube. The tube was removed intact, the broad ligament reefed, and the uterus suspended by modified Gilliam methods. The patient made an uneventful recovery and was discharged in two weeks perfectly well. The lantern slides and pictures showed the tube unruptured and, after being opened, the fetus *in situ*, measuring 5.5 cm. The case illustrated the following important points which were valuable in the diagnosis of tubal pregnancy: (1) There was in almost every case of ectopic pregnancy, ruptured or unruptured, a variation from the normal menstrual cycle of the individual. (2) Pain was present in 96 per cent. of the cases. (3) With unilateral pain plus bleeding in any case that had skipped a period, or was overdue at the time of the onset of symptoms, our first thought should be of ectopic pregnancy.

Dr. ARTHUR STEIN said that the points brought out in reference to the differential diagnosis of unruptured ectopic gestation were perfectly correct, but there were other conditions to be considered. At the Harlem Hospital they quite frequently made the diagnosis just as Dr. Chase had indicated, but they found that their diagnosis was incorrect in at least one-half of six consecutive cases. In several cases they found that they were dealing with a tremendous hematosalpinx twisted on its pedicle which gave exactly the same symptoms as an unruptured ectopic pregnancy. They had also observed these symptoms on a very old pyosalpinx, though that rarely happened. They were now a little more careful in studying these cases which one was likely to think of only as a case of ectopic pregnancy.

Dr. WILLIAM P. HEALY stated that this case permitted them to emphasize two points in the history and management of ectopic gestation. First, this woman had never been pregnant before, and in her previous history there was no antecedent history of pelvic inflammation of any kind. In the second place, the mass in the tube might have been taken for an enlarged corpus luteum of an early pregnancy in a retroverted uterus with threatened abortion. One must also consider the possible coincidence of an ectopic and a uterine pregnancy. It was necessary to bear this in mind so that one would not interrupt an intrauterine pregnancy by curetting.

Syphiloma Vulvæ.—Dr. ARTHUR STEIN presented this paper in which he said that the reason why the descriptive term "syphiloma vulvæ" was applied to the disease under consideration rested on both histological and clinical grounds. Histologically the hypertrophied masses of the diseased area were gummatous and subject to the familiar necrotic changes and cicatricial contractions seen in gummata. Clinically, the vulvar changes manifested themselves a long period, sometimes many years, after the primary infection. Moreover, luetic induration of the vulva was apt to supervene in the absence of all other specific changes after a long interval of apparent health, thus accounting in part for the many mistakes in diagnosis that had been made. The old term "esthiomène" being purely descriptive and therefore too general was advantageously replaced by a name distinctlvely indicative of the syphilitic origin of the condition. He was thoroughly convinced that syphilis was always responsble for esthiomène and that specific treatment in combination with operative removal of the hypertrophied tissue was followed by decidedly favorable results in those cases in which the syphilitic character of the disease was not demonstrable by the customary tests. Unquestionably an etiological part was occasionally played by malignant disease and by tuberculosis in the production of similar vulvar changes. If on bacteriological examination the tubercle bacillus was found the case was one of lupus pure and simple and was not related in any way to the disease under consideration. Primary malignant disease of the vulva in the form of epithelioma was of very rare occurrence and of more rapid growth than syphiloma, as he had shown in a previous paper. ("Primary Carcinoma of the Vulva," *American Journal of Obstetrics*, 1916, lxxxiv.) It was recently pointed out by Thorn that syphilis might exactly simulate cancer in any location, either in the viscera or on the surface of the body. The microscopical findings, however, definitely established the existence of malignant disease. The great majority of vulvar indurations, including those in which no tuberculous or malignant origin was demonstrable, should in the future be charged to syphilis and a suitable descriptive terminology employed. Elephantiasis vulvæ, applied to these cases, was also wrong. It should have been named pseudoelephantiasis, a condition which simulated true elephantiasis, a disease of an altogether different etiology. Scattered through the older literature illustrative cases might be found showing an endeavor to incriminate syphilis as the responsible factor in these cases. The writer described in detail the microscopical, gross, and clinical pathology of syphiloma. Clinically the disease was characterized by its painlessness, noninterference with the patient's general health, and disproportion between the local changes and the resulting disturbances. As a rule there was no itching, no tenderness on pressure, and no evidence of acute congestion. Until the condition had become complicated by ulcerations of the vestibule with more or less invasion of the urethral orifice and urethra causing painful micturition, or by perineal infiltration with anorectal involvement resulting in painful, sometimes bloody stools, the patients, as shown by the writer's personal observations and by cases reported recently by Gallagher and others scattered through the literature, were remarkably free from pain and other subjective symptoms. The treatment of syphiloma vulvæ was both surgical and medical. Operative interference consisted of excision and destructive cauterization of all tumors and excrescences. This radical procedure was usually effective and not followed by recurrence of the condition. Intravenous injections of salvarsan were an essential supplement of the surgical treatment. The prognosis was very favorable as was to be expected in properly treated gummatous changes of tertiary syphilis. Dr. Stein reported in detail two cases of syphiloma vulvæ coming under his observation at the Harlem Hospital, together with the laboratory report and the results of microscopical examination. He concluded as follows: (1) In conformity with modern knowledge and in the interest of a better understanding of the disease, all misleading names, such as esthiomène or lupus vulvæ, should be exterminated from the literature. (2) Syphiloma vulvæ correctly designated the disease as a manifestation of tertiary lues. (3) A positive Wassermann test was not essential in view of the long-standing character of the specific infection in the majority of cases. (4) The treatment under all circumstances was thorough excision of all tumors, hypertrophied tissues, and ulcers, followed at the same session by energetic cauterization, and combined with intensive antisyphilitic medication.

Dr. ELISE L'ESPERANCE said that she was interested in Dr. Stein's paper not only because she had had the

privilege of seeing the case at the Harlem Hospital but because so many of these lesions of the vulvæ had been passed under the designation of lupus from which they differed both syphilologically and serologically. She exhibited the gross specimens, which she said demonstrated very characteristically the enormous hypertrophy sometimes encountered in these growths. This specimen showed some hypertrophy, but was almost entirely made up of edema and ulceration, though it still retained its papillary character. The fact that it retained its papillary character was also interesting in that it placed it among syphilitic conditions, for it was generally accepted pathologically that most of these syphilitic lesions started as papillary structures. She hoped that Dr. Stein's classification would become permanent. These lesions were nearly always grouped under lupus and that was a very large term; it was to be hoped that in the future accurate work would depend upon Dr. Stein's classification.

Dr. MILTON A. SCHLENKER said he presumed these specimens were from colored patients. This condition was of a most common occurrence in the South, prevailing almost to an exclusion in the negro race. They did not make the same classification as Dr. Stein did. They referred to the solid tumors, which were usually pedunculated and globular, as elephantiasis, and to the sessile form which underwent ulceration, as condylomata. These latter were sometimes quite extensive in their manifestations, extending as far as the upper part of the thigh. These conditions were described by Dr. R. Matas, in his book on "Tumors Peculiar to the Negro Race." The former growths were not regarded as specific in origin, and were treated by simple ligation and amputation; the latter were looked upon as luetic and in addition to antisyphilitic medication, the excrescences were treated by actual cautery.

Dr. WILLIAM P. HEALY said they were accustomed to consider syphilis under three divisions—primary, secondary, and tertiary. So far as syphilis of the vulva was concerned they seldom saw anything but secondary manifestations. In tertiary syphilis one got a breaking down of the gummatous lesion and when one examined with the dark field for spirochetes he did not find them. One had to depend upon the blood test to make the diagnosis of syphilis. A condition of so-called elephantiasis was not uncommon among negroes, and it was not uncommon to have syphilis present with such a lesion. He was not sure that Dr. Stein was justified in including esthiomène with syphilitic lesions. Esthiomène was a term that was applied to superficial, very painful, chronic, incurable ulcers of the vulva, a condition the etiology of which was absolutely obscure, and no one but Dr. Stein had been willing to include it with syphilis as it did not respond to antisyphilitic treatment. Esthiomène was a condition practically incurable except by thorough excision. Neither did esthiomène respond to syphilitic tests. He thought the etiology of esthiomène still remained to be elucidated, and at the present time to describe the lesion as syphilitic was unwarranted. That there was a difference between esthiomène and syphiloma was further emphasized by the different modes of treatment of the two conditions. Esthiomène was treated by excision of the lesion while syphiloma was treated by excision and constitutional treatment.

Dr. LEON T. LE WALD mentioned several points in syphilis of the stomach related to syphiloma vulvæ as Dr. Stein had described it. In a case of suspected syphilis of the stomach, an authority on pathology sent back the diagnosis tuberculosis, but the tubercle bacilli could not be demonstrated. The pathologist then acknowledged that the condition found might very well be syphilitic. In other cases pathologists had reported at first examination that these conditions were tuberculous, but the confirmation that they were tuberculosis was not forthcoming, and many of these cases were no doubt syphilitic and would give a positive Wassermann reaction. In growths involving the stomach it was perhaps more important to make the differentiation between carcinoma and a syphilitic growth than in the case of growths in the vulva, because in the latter situation should the operator make a wide resection less serious consequences to the life of the patient would result than when the growth was located in the stomach. Among their cases they had had fourteen or sixteen, two of which they had considered as late manifestations of congenital syphilis. The cases which Dr. Stein had reported might possibly be delayed manifestations of congenital syphilis particularly as he reported that the case showed no evidence of acquired syphilis.

Dr. STEIN said that in regard to the question whether he would give antisyphilitic treatment even in cases in which the Wassermann was negative, he would say that it was difficult to obtain information with reference to congenital lues in these cases. On the other hand, as he had pointed out in his paper, in at least one case there was a probable luetic infection in the husband. So far as so-called "elephantiasis" in negroes was concerned, he was well aware of the fact that the condition was found among them, but the literature had very little to say on this subject. Elephantiasis was due to a well-defined infection; it was always due to filariasis. These cases referred to should be called "pseudoelephantiasis." Dr. Gallagher of Texas had just published four rare cases of syphiloma vulvæ in the negro which were entirely similar to the two cases reported by the speaker, so the condition could not be so very common in the South.

Dr. SCHLENKER said that Matas described the disease in a book published twenty years ago.

Dr. STEIN said that so had R. W. Taylor and others. Esthiomène, as he pointed out in his paper, was a disease *sui generis*, and up to a few years ago very few thought of syphilis as an etiological factor. As he had said before, Dr. Heiman and he published a case in 1912 which they called "esthiomène and secondary elephantiasis vulvæ" and he did not hesitate to say that this was wrong. It was a case of syphiloma of the vulva true and simple. If these cases were followed up it would be found that ultimately they could all be traced to syphilis. So far as he was concerned he was converted to that idea.

Gangrenous Appendicitis Coincident with Labor.—Dr. JAMES FRANCIS GRATTAN read this paper in which he reported an unusual case of appendicitis in which the initial attack occurred and operation was performed during the first stage of labor in a primipara, 24 years of age. He stated that he had been unable to find a similar case in the literature. The following facts added to the rarity of the case: (1) The patient was a primipara; (2) she had never had an attack of appendicitis or any type of abdominal pain up to the time of the event; (3) she had had a perfectly normal gestation course, promising nothing unusual. Early labor pains with abdominal symptoms occurred simultaneously, leading to the diagnosis of appendicitis. A totally gangrenous appendix was removed through a right lateral oblique incision four inches in length reaching from an inch above the iliac crest to a point one inch below and mesial to the anterior, superior spine. There was present a beginning peritonitis of a seropurulent character. A normally formed and developed full-term baby was delivered nine hours after the operation. The baby was in a state of apnea lasting forty-five minutes, with good pulse, followed by a normal period of three hours. There were recurrences of the apnea with normal periods between, with final failure of the baby's heart action, and death seven and one-half hours after delivery. The baby was probably toxic from the pus in the mother's appendix. This opinion was borne out by the almost fatal postoperative complications of the mother. She suffered from cardiac and renal failure, undoubtedly of toxic origin from the appendix. A subsequent jaundice gave evidence of the effect of the toxemia on the liver function. Complete recovery followed without residual pelvic exudate, and without cardiac, renal, or other residue of the complications, and without invalidism of any kind.

Dr. WILLIAM H. HASKIN said Dr. Grattan was to be congratulated on the very successful outcome of this remarkable case. He had described it very graphically but he did not think anyone could realize from a description the condition with which he was confronted. Though the girl was courageous she became neurasthenic and difficult to manage. Dr. Grattan was to be congratulated on getting the appendix out without rupturing it, in view of its large size and the fact

that the appendix was out of its usual location on account of the gravid uterus. He had never before heard of a complicating appendicitis in such a late stage of gestation.

Dr. GRATTAN stated that they had tried every chemical means available to find the cause of death of the child, but discovered nothing that gave any clue. He had followed the mother's urine all through gestation and found nothing abnormal. The albuminuria that developed was only of about twenty-four hours' duration. Toxemia due to the gangrenous appendix seemed the most reasonable explanation of the child's death and the mother's postoperative cardiac and renal failure. If the child's death was due to the morphine given the mother, they would not have been able to resuscitate it in the first place; the effect of the morphine would have been greater at that time than seven hours later.

Dr. STEIN said he thought Dr. Grattan was perfectly right in his assumption as to the cause of death in the child. In severe cases of eclamosia the child was sometimes born in a stupor and yet survived. In this case the toxemia was a little too far progressed; that was the plausible theory as to the cause of death.

Dr. GRATTAN, in reply to a question as to the temperature of the child, said the temperature was taken just after birth and once during the day and was normal. In fact the child seemed perfectly normal in the intervals between the periods of apnea. As Colonel Haskin had said, it was impossible to describe the amount of work attached to a case of this kind. He had been with the patient during four days following the operation, and during the third and fourth days the urine had been examined every few hours. The patient had had absolute suppression for twelve hours.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held December 5, 1919.

DR. SETH M. MILLIKEN IN THE CHAIR

Extensive Actinomycosis in a Soldier; Recovery.—Dr. WALTER M. BRICKNER presented this case which, he said, was exceedingly interesting from many standpoints: etiological, diagnostic, therapeutic, and clinical course. The patient was in an engineer regiment near the front when, on March 25, 1918, he noticed a red spot just above the left hip and at the same time had pain in the left testicle. On April 1, he entered a large base hospital and had a dressing applied to the hip lesion. He was put to bed, treated with wet dressings and an *x*-ray picture was taken. On April 11th he was operated upon for varicocele on the left side, although the records stated that he then had a large mass in the left groin! The wound from the varicocele operation apparently healed normally. On April 30th another *x*-ray picture was taken and pus discharging from the lesion near his left hip was examined. At this time he was losing weight and strength very fast. A small incision was made to permit freer discharge of pus from the sinus near the hip. It was thought that he had tuberculosis of the hip and on May 21 he was discharged to another base hospital with that diagnosis. On June 11, he was transferred, with the same diagnosis, to Base Hospital No. 3 where he then came under observation of the speaker in charge of the surgical service. He was weak, pale, emaciated (weighing less than 100 pounds), and had a small discharging sinus above the left trochanter, a purplish, inflammatory, hard plaque in the skin of the left lumbar region, and a mass in the iliac region above Poupart's ligament. He was first seen by Dr. Brickner with Dr. Celler (chief of the medical service) sitting as members of the Disability Board. The appearance of the skin involvement and the character of the pus from the sinus made both of them feel sure that the soldier did not have tuberculosis but actinomycosis. and this diagnosis was confirmed by the microscopic examination of the pus (by Dr. Denzer). With that diagnosis, Dr. Brickner said he would have done his full military duty if he had marked the soldier "Class D" and sent him back to the United States; but, since it would take several weeks before he could then get radical treatment, the boy would have lost the apparently small chance of survival that he might still have, so the speaker decided to give him that chance by immediate operation. X-ray pictures showed involvement of the ilium, but none of the hip or the lungs. The sinus was laid open down to the iliac bone and the involved portion of the bone cleaned out. The incision was then carried up into the loin and the inflamed skin area widely excised just as one would for carcinoma. Another incision was then made along Poupart's ligament where there was a large swelling, and the large retroperitoneal actinomycotic abscess evacuated. The iliac lymph nodes were extensively involved. Some were removed. Others, extending up along and too densely adherent to the external iliac artery were not removed, but were split open. Several sinuses were found extending down the thigh under the fascia lata, all containing pus. These were laid open. This brief statement of the operation gave but an inadequate idea of how formidable and extensive the procedure was. The patient was put to bed and kept continuously in the open air. Every pocket and angle of the huge wound was irrigated, at first twice, then once, daily with iodine solution; and the patient was as well fed as possible. In addition, large doses of potassium iodide—700 grains daily[!]—were administered, which huge dose did not upset the patient at all. The patient was also given two doses of salvarsan, but so far as the speaker was able to judge this produced no effect on his progress. A fresh skin involvement in the loin was excised in August. Towards the end of August the patient had gained many pounds, was feeling well, and the vast wound was almost healed. At this time Dr. Brickner was ordered from the Base Hospital to an Evacuation Hospital, and he urged upon the officer succeeding him as chief of the surgical service and upon the patient himself that the latter should not be discharged until the wound had been entirely healed for two full months. But the soldier was impatient as soon as he was apparently cured and the officer in charge finally yielded to his supplications and, on September 13, 1918, discharged him to the United States. While at Brest, October 10th, the wound was again suppurating and on the way home the soldier was very ill, but again responded, aboardship, to large doses of potassium iodide. He was sent to the General Hospital No. 3, Colonia, N. J. The speaker saw him again in New York in March, 1919—just a year since the first symptoms. He then had two pustules in the scars, about to break. At the speaker's suggestion, by letter, to Major Albee, these were incised and swabbed out with tincture of iodine, the administration of potassium iodide was resumed, and *x*-ray treatment added. Following this he had from time to time some slight local pustular recurrences in the scar; but for the past few weeks was apparently cured. To-night there was again to be seen a small pustule in the scar, which would no doubt heal, like its predecessors. when opened and iodinized. The soldier had not recently been taking his potassium iodide. It would be unwise to regard him as entirely cured or to discharge him from the army until several months elapsed with no further suppuration. It was very important also that he should continue to take large doses of potassium iodide. As seen to-night he was fat and strong.

Dr. GEORGE E. BREWER asked Dr. Brickner if he had any idea how the infection had taken place because it was in an unusual location. He also asked how long the administration of the potassium iodide was kept up and how large doses the man took.

Dr. EDWIN BEER said Dr. Brickner spoke of using 700 grains of potassium iodide daily—he would like to know whether that was necessary, whether that was better than using—say 15 grains. He asked this because it had been distinctly stated by those using potassium iodide in disturbance of the thyroid function that amounts above 15 grains were not absorbed.

Dr. BRICKNER, in closing, said that potassium iodide was the remedy recommended by the text-books for actinomycosis but it could not be regarded as a specific because many patients suffering from actinomycosis died in spite of potassium iodide. He had heard Dr. Moschcowitz say that he had never seen a patient cured by potassium iodide. This patient was not cured by potassium iodide alone. but by combination of a very extensive operation, the thorough persistent use of

iodine locally, and the iodide internally. Every pocket of the wound was irrigated daily with iodine solution (Lugol's or other). To-day the patient could stand about 70 grains of potassium iodide a day, intermittently; but while he was very sick in the summer of 1918, 700 grains daily did not upset him at all. It was possible that the potassium iodide tablets they were using in the army were not of the strength that they should have been. The important point was to give the iodide up to the limit of toleration. The speaker did not think that what applied to thyroid conditions in reference to potassium iodide applied in a case like this. Just as in syphilis, in some cases small doses might be insufficient but with large doses one got results. The point that Dr. Brewer brought up was the most puzzling feature of the case. The infection was apparently not contracted through the respiratory or gastrointestinal tract. The source of the infection in this case was unknown. Another feature of interest was that with such an extensive local involvement, extending into the iliac bone up into the lumbar region, into the retroperitoneal nodes, and down the thigh, there were no metatases, and no extension, after operation, beyond these areas. Recent *x*-ray pictures show no lung involvement. Dr. Brickner said he had seen patients with localized actinomycosis recover, but he had never before seen so extensive a case as this one that did not develop metastases or die before metastasis took place.

Fracture of the Humerus Treated by Traction.—Dr. KENNETH BULKLEY presented this patient as a text to lantern slides presented. This patient and the lantern slides illustrated a point not always appreciated, the necessity of external rotational deformity correction. It was the early result that he wished to show particularly. It was now about two months since this patient had fractured her humerus. She was treated by suspension and traction and by mobilization, not immobilization. Forty-eight hours after the fracture was treated she was able to touch her shoulder joint and to extend the arm fully. At the present time the *x*-ray showed that she had a good callus. Dr. Bulkley then exhibited lantern slides that emphasized the importance of external rotation and that the forearm should be extended on a bar at quite a distance out from the bed. Another point was that with the traction band still on the humerus and extension bands still on the forearm, the patient was allowed out of bed before union was firm, and while angulation still potentially existed. By night the patient was again suspended, the angulation disappearing by morning. While the patient presented had practically perfect function, the lantern slides of another patient, of practically the same age and having a fracture exactly similar but treated by the application of plaster of Paris, showed a great deal of functional disability, inasmuch as she could not get external rotation further than a right angle, and that was a distinct disability.

Dr. MORRIS SMITH said that in gunshot wounds it seemed to him this method of treatment should be given a very careful and thorough trial. It would be especially interesting to know whether fractures of the neck of the humerus treated in this way would give as good results as fractures of the shaft.

Dr. MILLIKEN said that this was certainly a satisfactory method of treating fractures of the humerus. He had seen a case of Bellevue Hospital which Dr. Bulkley had treated in this way, a man 70 years of age with an oblique fracture of the humerus. After four weeks the man had practically perfect function.

Dr. SEWARD ERDMAN asked if this method would be applicable to fractures of the humerus with non-union following bone grafting.

Dr. BULKLEY, in closing, replied that he had not had any experience with the method in non-union following bone grafting in fracture of the humerus, his cases having all been primary fractures and not pathological ununited ones. This method rather operated for the prevention of nonunion. The mobilization promoted circulation and one was not so likely to get non-union as when the fracture was put up in plaster of Paris. In a series comprising some hundreds of cases he had not as yet encountered a case of non-union following this method of treatment. He wished again to emphasize the fact that the method allowed of union with a degree of external rotation which it was impossible to obtain with any of the various types of ambulatory treatment with which he was acquainted.

Aseptic Amputation of the Rectum.—Dr. EDWIN BEER presented this patient, a woman 52 years of age, admitted for strangulated femoral hernia, December 21, 1915. On examination of her rectum for hemorrhoids, an extensive carcinoma of the anterior wall involving the wall of the vagina was discovered. On January 5, 1916, four years ago, an asceptic amputation of the bowel as was described in the paper was performed. The patient did not suffer from ligation of the bowel until forty-eight hours had elapsed, when the ligature was opened and the tube tied in place. Owing to the fact that the whole posterior wall of the vagina as well as a large piece of the sigmoid, together with the rectum, had been removed, the patient was kept in bed for twenty-four days. During that time the wound rapidly healed and she was discharged from the hospital practically healed, on February 12, 1916, thirty-eight days after operation. She was at the present time free from recurrence. He had hoped to show two other cases but they had failed to appear.

Dr. BEER then read a paper in which he said that in presenting the following modification of amputation of the rectum as usually practiced, he did not wish to give the impression that he was describing an entirely new procedure. Before the New York Surgical Society some years ago (Annals of Surgery, Vol. 66, pp. 241) he presented several cases in which he carried out the technic about to be described. The great advantage that he saw in this technic was in the rapid healing of the large wound made by the excision of the rectum and lower sigmoid. By this method patients could be discharged from the hospital with the wound closed in a relatively short time and it was to call attention to this that he was again presenting the subject before this Society. The first step in the operation, the patient's intestines having been thoroughly cleaned by two courses of castor oil, was to shut off by suture the anal opening. With a separate set of instruments a skin flap was turned up all around the circumference of the anus, and with a heavy silk suture this circular skin flap was sewed together so as to prevent any leakage of the intestinal contents during subsequent manipulations. (Fig. 1.) This area was then well painted with iodine and covered with a towel. After putting on a fresh gown and gloves, with fresh instruments the surgeon then exposed the rectum with an incision well above the perianal denudation and running at a little to the left of the median line. The coccyx was removed in the usual way and the rectum liberated well above the growth. Douglas' pouch was opened and the sigmoid was drawn down as far as necessary, and, after sufficient of the sigmoid had been liberated to warrant the surgeon in believing that he was above the growth and the glandular involvement, the peritoneum was closed at the new level on the sigmoid and the skin incision was continued down to either side of the anus, meeting the denuded area which was made preliminary to the closure of the anus. After liberating the anus from all its attachments, the rectum, sigmoid, and anus, unopened, were thrown over on the patient's sacral region. The levator ani muscles are united to make a firm pelvic floor and a tube is inserted in the most dependent part of the wound where the anus originally was. Skin stitches are inserted and a small packing introduced up to, or close to, the suture line in Douglas. With a heavy silk ligature the protruding gut was tied off by about one-half inch from the lebel of the closed skin wound and a clamp was placed across the bowel about one inch distal to the ligature. The intestine was sutured to the skin without entering its lumen so as to attach the gut at the new position (artificial anus). A small packing was inserted above the new position of the gut. The whole wound was then dressed, the gut still being attached, after a vaseline dressing was applied to the large wound with the cautery resection was made between the ligature and the clamp. In this way the lumen of the bowel had not been opened until after the wound had been sutured and dressed. The ligature was allowed to remain in place until the patient complained of distention or became distressed by cramp-like pains. Then to give relief the ligature was opened and a rectal tube

was introduced well into the bowel and held in place by a purse-string suture, which tube continued to protect the wound, now well on the highroad to complete healing from contamination by the fecal current. He recommended this method of aseptic amputation of the rectum, as it saved the patient a long stay in the hospital. The average stay of patients operated on in the older way with the peritoneal cavity opened was well over eight weeks, as opposed to twenty-eight days in these cases. Moreover, by keeping the wound free from infection the nursing and house staff were spared a lot of unnecessary work and the patient a great deal of discomfort.

Dr. WILLIAM C. LUSK stated that he had performed aseptic removal of the rectum by the combined routes, through the preliminary construction of what he termed a *left subcostal colonic vent*, which consisted in an opening in the descending colon, made just below the extremity of the left 11th rib, of sufficient size for the introduction of a large sized catheter. This *vent* served the following purposes: Before the abdominal operation (1) It enabled one to wash out the lower bowel through and through from above downward. (2) It allowed the escape of practically all the gas from the intestines, so that at operation the latter were fully collapsed. At the abdominal operation (3) After sectioning the sigmoid, it afforded the opportunity to close tightly by suture, the proximal segment of gut, after the latter had been drawn through an opening in the abdominal wall for the construction of an artificial anus, without the supervention of intestinal obstruction, thus permitting union of the abdominal wounds to get well advanced before the artificial anus was established. Following the abdominal operation (4) *Of greatest importance* was the advantage, that immediately upon completion of the operation, water could be administered to the patient through the vent. (5) When the proximal bowel end was finally opened up, the size of the aperture could be controlled. (6) After the artificial anus had been established, while the patient was lying in bed convalescing, enemas given through the vent evacuated the bowel very completely, thus avoiding involuntary movements.

The left subcostal colonic vent was constructed as follows: An incision, about five inches in length, was made half an inch below the forward extremity of the left 11th rib and parallel to the latter. The peritoneum was opened opposite the tip of the 11th rib, and the incision in the same was enlarged backward up to the site of retroperitoneal attachment of the descending colon. The lower flap of peritoneum was pulled over the muscular portion of the lower lip of the abdominal incision and was attached by two sutures to the outer surface of the external oblique muscle. The upper flap of peritoneum was sutured to the deep muscular margin of the upper lip of the incision. A cone-shaped fold of the descending colon, picked up by a thread, was drawn out into the wound and made to overlie the peritoneal flap covering the entire thickness of the muscles in the lower lip of the incision, its apex reaching as far as to the level of the outer surface of the external oblique, in which position it was then made fast by sutures. To the upper lip of the incision, only the base of the cone-shaped fold is attached, suture being made along the line of emergence of the process of bowel from the peritoneal cavity. Thus a double triangular fold of bowel was brought well out of the peritoneal cavity, the lower surface of which was fixed over the structures comprising the whole thickness of the abdominal wall, while its upper surface was left free in the wound to furnish the site for subsequent puncturing of the gut. Two loops of Pagenstecher thread catching this exposed surface of the bowel, were left *in situ* for the purpose of locating the bowel when the opening is made after three or four days. Gauze packing should protect the upper free surface of the cone-shaped fold of colon lying exposed in the wound from becoming buried in adhesions. Dr. Lusk said he would also like to draw attention to the fact that it was often impossible to liberate the lower bowel from its high attachments in the pelvic cavity, through the sacral route. This could be due to a too narrow pelvic cavity, or a too short attachment of the sigmoid. Comparatively often the pelvic cavity was too narrow for the superior hemorrhoidal vessels to be ligatured and severed from below. Sometimes it was so narrow that the knuckles could not be gotten through the pelvic outlet. Johae in 1893 had established a relationship between the distance between the posterior superior iliac spines and the size of the pelvic cavity. The speaker said that in cadavers, without making any allowance for a tumor of the rectum, he had found that where the distance between the inner surfaces of the posterior superior iliac spines measured no less than 2¾ inches, he was able to reach the superior hemorrhoidal vessels for ligature. If the measurement were but 2½ inches, one attempting a high liberation of the terminal bowel was very sure to have trouble from lack of room. As to the ability to descend the lower part of the sigmoid flexure by the sacral route, the possibility of sectioning the mesosigmoid in a way to preserve its arterial arcades in association with the liberated bowels had to be taken into consideration. Occasionally a sigmoid had no free portion at all. An *x*-ray of the sigmoid flexure could give some idea as to its redundancy.

Dr. JOHN DOUGLAS congratulated Dr. Beer on his excellent results. He asked with reference to the bowel control—if the patient had control and how she could use a cup, or what method of collecting the feces she employed, since with an anus in this position it would be difficult to use a colostomy cup such as they used with a high colostomy or even use an ordinary toilet seat. Another point, which Dr. Lusk spoke of, was bringing the sigmoid down in a narrow pelvis. He had found this difficulty in the sacral operation. In many cases in which he had hoped to do a radical operation he found metastases in the peritoneum or in the liver where they had been undiscovered when operating through the sacral route. If one continued to do the sacral operation he would have many disappointing results because of these metastases.

Dr. ROBERT T. MORRIS said he had not done this operation but he intended to do it. After the old operation of bringing down the sigmoid he had obtained pretty good results. In reference to the matter of bowel control, his patients had used a hollow rubber ball fastened to a perineal strap attached to a waist band, but with this arrangement it was necessary to immerse the ball in melted tallow frequently enough to keep it covered with this unirritating coating.

Dr. WALTER M. BRICKNER said the question of control was not concerned in the paper; but since it had been brought up in the discussion he would like to say that "control" with an artificial anus was not a question of location but largely a matter of training the patient and the patient's bowels. It had been his experience that, after amputating the rectum for carcinoma if the stools are kept solid by careful selection of the diet and the patient is trained to move his bowels once a day at a certain time, he would not be seriously inconvenienced, and, even with a "sacral" anus, could use the toilet seat. The only trouble such a patient was likely to have was when, from some unsuitable article of diet or from other cause, he had a transitory diarrhea. Dr. Brickner related that in France he had had under his care a young marine who was crawling face down in the Belleau Woods offensive, when an "high explosive" tore away his anus. When received at Base Hospital No. 3 he had simply a scar at the site of the anus, with no sphincter action, and a great deal of the glutal muscles had also been removed on each side. He had no control over his bowels and was continuously lying in his own feces. It was a question whether to perform an inguinal colostomy, in which event the control might be no better, or to attempt a restorative operation on the rectum and anus, or to train the bowel and select the diet. Before deciding on the latter, Dr. Brickner excised the anal scar to search for possible sphincter fibers, but there was no trace of these nor of available levatores ani; and even the doubtful expedient of attempting to fashion a sphincter from the glutei was impossible because so much of these muscles were absent—either because of the shell wound itself or as a result of the operation of débridement. In spite of the limitations of the hospital dietary—far different from that of a civilian hospital in peace—it was possible to select feeding that "constipated" the patient (at first with the help of opium), and soon his bowels were so regulated, with training, that he used the

latrine once a day, like the other soldiers and he practically never soiled himself. He now lives in Chicago and recently wrote to the speaker that he is "well and happy" and conducts his business as a traveling salesman with "very little discomfort."

Dr. MILLIKEN asked Dr. Beer what the pathology was in the case he had reported, whether it was adenocarcinoma and whether part of the sacrum was removed or just the coccyx.

Dr. BEER, in closing, said that two years ago he had seen a case operated upon by Dr. Lusk by the procedure he had described with the most ideal result. He asked Dr. Lusk whether there had been any recurrence in that case.

Dr. LUSK replied that there had been a slight recurrence, and he had operated again this fall.

Dr. BEER said he was not recommending this modification of the sacral operation for high carcinomata. Recent statistics of operation for rectal carcinoma, high and low, operated upon by the "Kraske" route as published in *Surgery, Gynecology, and Obstetrics*, Vol. XXI, page 496, by C. Davis, showed 68 per cent. recurrence. There was no doubt but that there were very definite limits to the sacral route. The operation he had described was not the typical "Kraske" with resection of the sacrum. Sixty-eight per cent. of recurrences meant that in trying to take out the carcinoma by this route portions of the carcinoma were left in, and this was all the more likely when high tumors were attacked by this route. The patient just presented was especially interesting in this connection since after freeing five inches of the bowel above the neoplasm, he found it necessary to remove an extra piece about four inches long as there was a mass well above the Douglas pouch as large as an egg, above the originally liberated gut. If this had not been detected the patient would have died of her metastases and would not have been well now, almost four years after operation. This was only another illustration of the fact that if the operation was extensive enough one could get out all of the tumor in many cases, and that was true of carcinoma of the stomach, breast, bladder, etc. He would not say that this patient was cured, but it was now four years since the operation, so it seemed that we might assume that she was cured. The second patient in whom he did the same radical operation was well at the end of three years. The modification was simple and made for rapid healing as the bowel was not opened until after the dressings were applied, so that there was much less likelihood of infection of the large wound. He believed with Dr. Brickner that if we put these patients on a proper diet and trained them to have one movement a day they would have control of their bowels even though they had no muscular sphincter. Control of gas they never acquire. This patient wore a pad but it was perfectly clean, and never became soiled.

A Consideration of Surgical Hazards in Diabetic Patients.—Dr. NELLIS B. FOSTER presented this subject. He stated that on account of his interest in the subject of diabetes it had been his experience to see a large number of surgical complications in diabetics. These were difficult to handle and yielded a high mortality. He had gathered statistics from three hospitals and analyzed them and it was to the deductions from this analysis that he wished to call attention, because they were of as much interest to the surgeon as to the internist. Of the fatal cases of diabetes seen in hospital practice beyond the third decade of life, 60 per cent. died following surgical operations, and of the fatal surgical cases 70 per cent. died in coma. He had been astonished to find that diabetic coma occurred as frequently in what supposedly were mild cases as in what they considered moderately severe cases. The mortality following operation was higher with some types of minor surgery than with some conditions that required major surgery. In other words an operation for a cellulitis in a diabetic was more dangerous than an operatoin for a scirrhus carcinoma of the breast, other conditions being equal. These figures were to him so astonishing that he spent considerable time analyzing them to determine the factors in the surgical hazard, how these could be estimated, and how they could be reduced. The old conception of diabetes was that it was a chronic glycosuria when the patient was on a normal diet, but it had been learned that a patient might have no glycosuria and yet be diabetic. The old definition was not adequate. A chronic hyperglycemia was characteristic of the diabetic. Any individual having diabetes for a long time was prone to develop a nephritis of the interstitial type and when it reached a certain degree of intensity sugar was no longer found in the urine. The blood sugar was therefore the index upon which we must depend not only in determining whether we had or had not diabetes but also the degree. Cases that were thought to be mild were not so when judged by the blood sugar, and that explained why the mortality was as high with supposedly mild cases as with the severe cases. What was the effect on the blood sugar of infection? Infection in the normal individual caused abnormal blood sugar, and when the diabetic had an infection it produced not only the usual effect of an infection on blood sugar but superimposed this effect on the diabetic condition, and this meant that whereas the ability of the diabetic to burn sugar was decreased the infection permitted him to burn even less than he ordinarily did. The immediate effect of his inabilty to burn sugar—this diminished carbohydrate assimilation—was that acidosis resulted. It was known that many infections not surgical were associated with ketonuria. When the diabetic developed infection if he had no assimilation of carbohydrate he was sure to become intoxicated by acid bodies. Thus it was that the blood sugar went up as the reparative processes went down, and because there was more sugar in the blood bacterial growth was advanced; an explanation offered might be that sugar was a favorble medium for bacterial growth. Thus a vicious circle was established, whereby the blood sugar increased the infection and the infection favored the increase in the amount of blood sugar. That was exactly what happened in individuals who were poor surgical risks. If the blood sugar was anywhere near normal (0.15 per cent.) the patient might be a safe surgical risk. The immediate factor was the acidosis. As was well known, following operation there would be some acidosis and if the patient already had a certain degree of acidosis before operation the probability was that he would not survive operation more than forty-eight hours. The amount of acidosis could be determined by the carbon dioxide combining power of the blood. If the carbon dioxide combining power of the blood was below 30 the patient would not survive the operation more than twenty-four or forty-eight hours. The speaker had yet to meet the first instance in which an individual had survived operation under such conditions. By these tests one could determine those cases in which operation would be futile. Of course one could not control the infection hazard. It was important to remember that when these cases were seen early one could accomplish by slight surgical procedures what later would require radical surgery. The diabetic hazard could be determined if one had time. If the individual must be operated upon at once this hazard must be determined by the acidosis quotient, but if forty-eight hours were allowed many individuals showing a considerable degree of acidosis might be rendered fairly safe risks. If, for instance, a patient showed a carbon dioxide combining power of 25 they brought the carbondioxide combining power up to 50 and then with suitable treatment after operation and a due regard for the diabetic condition during operation the patient might be carried through safely. Ether was always contraindicated. It was known that glycosuria frequently followed the administration of ether. Ether aggravated the diabetic state and could not be used without extreme risk. In diabetics who had to be operated upon as emergency cases the post-operative care was most important, and was directed entirely toward protecting the individual from coma.

Dr. ROBERT T. MORRIS said he was glad Dr. Foster placed emphasis on the blood examination. He had felt that reducing the amount of sugar in the urine and lowering the acidosis to a safe point had made it proper for him to go ahead with operative work in diabetic patients not infrequently, and he had used bicarbonate of sodium in the Murphy drip after operation, and had kept the patient under the observation of internists. Dr. Morris said he had another suggestion to make which was perhaps speculative in relation to the ques-

tion of patients not resisting infection when there was a high degree of blood sugar. The body cells in order to make enzymes in a normal manner for meeting antigens needed a definite charge of water. Sugar was hygroscopic and took up water from all body cells, the process being in the nature of an exosmosis, and hence the cells deprived of water could not attend to the formation of protective enzymes or antibodies. That might be speculative but it gave a working hypothesis.

Dr. JOHN DOUGLAS asked Dr. Foster whether gas oxygen anesthesia increased acidosis and whether it was safer than ether. Personally he knew of no harder problem than when, where, and how to operate in diabetic gangrene. The determination of the blood sugar was most valuable and he was glad to learn this method of estimating the amount of acidosis as an index of operative danger. Dr. Foster spoke of sugar causing small contracted kidney. Sugar also caused arteriosclerosis. It seemed to him that not only was infection a determining factor as to what one was going to accomplish in diabetic gangrene, but that the amount of arteriosclerosis was also a determining factor. Before he knew about the blood sugar he had determined whether or not a patient with diabetic gangrene was going to get through an operation and particularly where to operate by the amount of arteriosclerosis present. The accurate laboratory methods of determining these other things were going to be a tremendous amount of help. He was particularly anxious to know how much acidosis was caused by gas oxygen anesthesia as he had lost a case of carbuncle of the neck so anesthetized and he had done amputations under spinal anesthesia and yet the mortality was still high enough to be discouraging.

Dr. JOHN C. A. GERSTER asked Dr. Foster to tell them what the status of the Allen treatment was at the present time. He cited an instance of an old man who was on the Allen treatment and was becoming more and more drowsy. The Allen treatment was discontinued and the man became better, and he thought that possibly in this case the man was suffering from the acidosis of starvation rather than that of diabetes.

Dr. BRICKNER asked Dr. Foster to tell them something of the pre-operative and post-operative care of diabetic patients. He was not sure that the use of bicarbonate of sodium was always useful. It was clear that the surgical prognosis in diabetes depended upon whether one was dealing with an incidental condition or a condition resulting directly from the diabetes itself.

Dr. FOSTER, in closing, said the Murphy drip was one of the recognized methods of administering alkalies and fluid to counteract acidosis and it was perhaps the best method of administering large amounts of fluid in a short period of time. He had often speculated in reference to the dehydration of which Dr. Morris spoke; this was one of the things about which they did not know much. In diabetic cases at autopsy the most striking thing was the dessication of the tissues. There was no other condition in which there was such dessication except diphtheria, where the pateint might have anuria from lack of water, but dessication of the diabetic was more marked in the young than in the type of cases seen by the surgeon. In reference to gas-oxygen anesthesia, he had carefully studied the blood in normal individuals after gas-oxygen anesthesia and he could not find that the acidosis index was materially increased. He felt convinced that there was some other factor responsible for the fact that the results of gas-oxygen anesthesia were not as good as one would expect theoretically.

Dr. DOUGLAS asked whether gas-oxygen was as bad as ether.

Dr. FOSTER replied that it seemed to be. For the diabetic the best anesthesia was local anesthesia. This did for large carbuncles, but of course there were cases in which general anesthesia had to be employed.

Dr. DOUGLAS asked what the effect was of large amounts of hyosine and morphine.

Dr. FOSTER replied that diabetics did not stand morphine well. The ideal anesthetic for the diabetic had not yet been discovered. With regard to arteriosclerosis and the results in gangrene, it was curious that in patients having one type of gangrene of the lower extremities starting on the toe and extending to the bone of the foot, if one took an *x*-ray of the foot in a series of cases the majority would have enough calcium salts in the arteries to give a perfectly clear picture, so that one could trace out the arteries on the *x*-ray plate and yet the fact remained that many of these cases cleared up but the arteriosclerosis was fixed. There were two different types, one with endarteritis obliterans in which restitution could not be imagined and another type in which the arteries were large and stiff, but the lumen patent. In many patients having infections the infection would clear up and a great deal of the limb could be saved by careful diet over a period of time. It was an advantage for that type of patient to have a course of dieting before operation. He did not wish to give the impression of dogmatizing, but there were two types of cases, one responding to treatment, namely, that type associated with infection and another type, endarteritis obliterans, and that was hopeless. About the Allen treatment, there were many in the beginning who advocated the starvation diet; it was new in their experience and because it was new they thought that by its use they could eliminate acidosis. While the Allen treatment was a distinct addition to medicine for which Dr. Allen deserved credit, they had to find out when it was applicable and when it was not applicable. It was thought proper to starve any individual who had acidosis. Now they knew that it was fatal to starve some of these diabetics just as it was fatal to give them ether. A differentiation must be made. The patient whose blood analysis showed an increase in the acidosis index after the administration of carbohydrate might by rest in bed, proper diet, and judicious handling be brought to a more nearly normal condition. With regard to the preliminary treatment of surgical cases of diabetes, if the individual had pus it must be evacuated. Usually it was a superficial infection that could be handled under local anesthesia, and the least possible operative procedure should be done at that time. The acidosis should then be determined by blood analysis and if the individual showed acidosis he might be fasted for a day to see what happened in the alkali reserve. The standard method of treating acidosis was by alkalies, but there were very few patients saved from diabetic coma by the administration of alkalies and only a few cases brought out of diabetic coma by intravenous injections of alkali.

X-Ray of Pneumoperitoneum Due to Perforated Gastric Ulcer.—Dr. FREDERIC W. BANCROFT presented this report with the accompanying *x*-ray plates. He stated that this was an *x*-ray of a case of perforated gastric ulcer that was admitted to the Second Surgical Division of the New York Hospital. It was taken in the prone position immediately upon admission and the patient operated upon without waiting for the development of the plate. Knowing of the *x*-ray work on pneumoperitoneum he had felt that the presence of free gas ought to show in cases of ruptured gastric or duodenal ulcer. Clinically one recognised this by the absence of liver dullness. This large air space shown in the *x*-ray under the diaphragm could easily be recognized under the fluoroscope. There were some cases of emphysema where liver dullness was diminished and this procedure might be a diagnostic aid in such a case. Recently at the New York Hospital they had had a man admitted with general peritonitis with liver dullness diminished. due to emphysema, in whom it would have been a decided help in the diagnosis.

Dr. CHARLES GOODMAN said this presentation was very timely as they were now making injections of oxygen into the peritoneal cavity for diagnostic purposes. He believed that when the indications and technic were worked out the method would become more popular and more frequently used. He had injected a number of patients and obtained some interesting pictures, the outline of the kidney, the liver, spleen, and pelvic organs. Dr. Gottlieb, their radiologist, had found that two liters of oxygen sufficed to bring out a clear outline and more than that the oxygen was not absorbed as rapidly as they had thought, but remained in the peritoneal cavity as long as two weeks after it was injected. It had occurred to them to see if the oxygen remaining in the peritional cavity brought about a change in the blood picture, and according to his suggestion blood counts were made immediately preceding the injection of oxygen

and at the end of twenty-four hours after the injection. It was found that in each instance the blood count increased from 80,000 to 530,000 erythrocytes. Cases examined were those of kidney tumor, empyema, subphrenic abscess, pelvic tumor, and ulcer of stomach. In one case the blood count increased from 3,960,000 to 4,800,000; in another from 4,000,000 to 5,600,000; in others from 4,000,000 to 4,080,000; 3,680,000 to 4,160,000, and 5,730,000 to 6,260,000. Dr. Goodman said he did not know whether others had made such observations or whether they would be of therapeutic value, but the fact remained that the red blood count was increased by the injection of oxygen into the peritoneal cavity.

Miscellany.

The New Jugoslavic Medical Schools.—In the city of Agram, otherwise known as Zagreb, a faculty of medicine has been organized and there are enrolled for the first two years of study 200 Servians and from 600 to 800 Croats, Slovenes and others. The official language is Servian, and German is banned here, as it also is in the city gymnasia. An anatomical building and clinic are already in use. Some of the faculty are as follows: Mickulicz has the chair of experimental medicine and pharmacology; Perovic that of anatomy; Zarnith of histology; Smelouka, physiology, and Zivitch prosector. There are in Agram a Sisters' Hospital, an orthopedic hospital with electric and mechanotherapeutic installation and a bacteriological institute directed by Gutschky, formerly of the Pasteur Institute, which is provided with an antirabic service. The creation of a medical school at Agram was necessitated by the wrecked condition of Belgrade, but in time the old university at the latter city will be restored to usefulness. A third Jugoslavic medical school will soon be established in some Slovenic city.

Belgrade has the nucleus for a school and faculty in the Public Health Office, the surgical hospital, a general hospital, military hospital, ethnographic museum, etc. The surgical hospital operates a laboratory for the special study of pathology and parasitology, and a tuberculosis department. The general hospital has a special clinic for skin and venereal diseases directed by a graduate of the St. Louis Hospital of Paris. The military hospital operates clinics for the eye, ear, nose and throat and a dental clinic. Thus far the medical school of the future is sure of an anatomical department and dissecting room and sections of physiology, chemistry, physics and forensic medicine. —*La Presse Médicale.*

Death of Professor Luciani.—The celebrated physiologist of Rome died on June 23, last, at the age of 79. His early education was obtained from the Jesuits. For certain reasons he did not take a University degree, but after two years spent in literature, philosophy and politics he chose medicine as a profession. He spent two years at Bologna but changed to Naples in the third year because of the milder climate and the chances for studies under certain professors of that university. Here contact with Albini, De Martino and Schrön opened up new vistas in his mind. Nevertheless he returned to Bologna for graduation in 1865 and afterward held assistantships in ophthalmology and physiology at his alma mater. Having chosen the latter as his life work he studied two years under Ludwig (1872-4) and then became professor of pathology at Parma for 5 years. His professorships in physiology were at Sienna, 1880-2; Florence, 1882-1895, and Rome, 1893-1917. His original work has been chiefly performed in physiology of the heart, cerebral cortex and cerebellum, muscular movements and fasting. He supervised the activities of Succi, the professional faster, thereby placing these feats upon a rational basis, and made an extensive report on them.

Not so long before that period professional fasters were regarded as tricksters. He furnished a scientific background to the work of Krauss on cerebral surgery, inspired Benedict's voluminous research on inanition and corroborated the teachings of Gordon Holmes on wounds of the cerebellum. It is said to be almost unique for an Italian medical text book to go through five editions, but this happened to his book on physiology which was also translated into English, Spanish, and German.

Prophylactic Vaccination Against Apoplexy.—Ferrán, the distinguished Spanish bacteriologist, is contributing a serial article on this subject to *El Siglo Medico.* His theory is simplicity itself. The vascular changes which make possible rupture of the vessels are infectious in origin and due to familiar pathogenic germs. We have only to isolate them and prepare autovaccines or make use of polyvalent stock vaccines and thereby arrest the degenerative process. There may be seen even more to it than merely neutralizing germ activities for the author surprised himself by curing a congenital nevus vasculosus by a single injection of one of his cultures. Until the article is finished no serious comment can be made concerning it. Ferrán was one of the first men to take up the subject of vaccines and serums and was even active in this field before Koch and the leaders of the Pasteur Institute. Today he is practically at the head of epidemiology in Spain and upon him has been placed the responsibility for preventing the recrudescence of influenza in his native land.

Malaria in old Corinth.—Under the direction of American Red Cross physicians and engineers, the Greek authorities are providing the town of old Corinth with pure water and a modern drainage system. Recently fourteen children died in the town of blackwater fever—an alarming number in a population of 1,000—and the people are thoroughly infected with malaria as a result of the mud and seepage which has drained into the excavations, abandoned since 1917, and which affords a breeding place for mosquitoes. Thousands of Americans visit this place in peace time. Here stood the old city of Corinth at the foot of the great rock, Acrocorinth, and here extensive archeological investigation has been carried on by the American School at Athens. The excavations will be drained and thoroughly kerosened, and the ancient system of sewers, cisterns, tunnels, aqueducts, and wells will be cleaned out. The Red Cross will co-operate with the Greek Department of Antiquities in making this area healthful for the native population and the thousands of visitors.

OBSERVATIONS ON THE EPIDEMIC OF INFLUENZA OCCURRING IN THE U. S. NAVAL HOSPITALS IN PHILADELPHIA IN 1918.

BY JUDSON DALAND, M.D.,

PHILADELPHIA, PA.

COMMANDER (M.C.), U.S.N.R.F.; MEDICAL CONSULTANT TO THE U.S. NAVAL HOSPITAL, LEAGUE ISLAND, AND THE U.S. NAVAL HOSPITAL, PHILADELPHIA.

THESE observations are based upon a study of the more serious of about three thousand cases of influenza occurring among the officers and men in the U. S. Navy in Philadelphia. Most of the patients were between the ages of twenty and twenty-six years and were in unusually good physical condition.

Influenza appeared in the British Army in May, 1918, and was brought to Philadelphia by ship. The first case of influenza was diagnosed on September 12, 1918, at the U. S. Naval Hospital, League Island, unrecognized cases having occurred earlier. At first the epidemic resembled that of 1889-90, but quickly marked differences were observed, such as a greater toxicity and mortality, susceptibility of young adults, and partial or complete immunity of those past middle age.

The epidemic was characterized by extreme contagiousness, rapid onset, early and rapidly developing adynamia, cyanosis, and a high rate of mortality. The period of incubation averaged from one to four days.

The U. S. S. *West Gaylock* sailed from an uninfected port in California, arriving at the Philadelphia Navy Yard on November 19, 1918. Although the epidemic was subsiding, 35 men were admitted to the U. S. Naval Hospital with influenza differing in no respects from cases observed during the height of the epidemic in October. This observation disposes of the theory that the virulency of influenza diminished at the end of an epidemic, and supports the idea that the disease disappears because most nonimmunes have been infected.

Influenza may be clinically classified as mild, ordinary, severe, or toxic. The toxic variety may be subdivided into pulmonary, circulatory, nervous, gastrointestinal, and renal.

A typical example of mild influenza occurred in a sixteen-year-old girl, who was suddenly seized with headache, backache, pains in the extremities, malaise, and attacks of slight or moderate perspiration, occurring two or three times daily. In the beginning the cough was slight, infrequent, dry, later becoming more frequent and accompanied by a small amount of mucopurulent sputum, containing many influenza bacilli. Auscultation revealed a few dry bronchitic rales in both lungs, and an extremely feeble respiratory murmur at both bases. The muscular element of the first sound of the heart was extremely weak and this organ did not react to the stimulating effect of fever. The pulse was easily extinguished by slight pressure and was less frequent than the fever would indicate; the systolic and diastolic pressures were low, and the pulse pressure large. The fever lasted but a day, coryza and sneezing were absent, the eyes were unusually brilliant, and the vessels of the ocular conjunctivae injected. During the first four or five days the only symptoms complained of were headache, weakness, frequent attacks of moderate perspiration, diminished appetite, and constipation. The urine showed no important change. Despite these few symptoms and the brief duration of fever, weakness continued, necessitating rest in bed for ten days. On the tenth day extreme fatigue was caused by sitting up for thirty minutes. Two weeks later the patient was improved, but weak, and required two weeks' rest at the seashore before complete recovery was secured. This case typifies an extremely mild influenzal infection, with ephemeral fever occurring in one previously healthy and illustrates the severity of the toxemia in a mild case of influenza.

Ordinary Influenza presents the same symptoms and signs as mild influenza, excepting that the fever, usually remittant in type, continues for four or more days, the pain in the head and extremities is more severe, cheeks more flushed, conjunctival vessels more injected, eyes brilliant, exhaustion more pronounced, lips cyanotic, and the few dry rales later become numerous and moist.

The urine shows occasionally a trace of albumin and a few granular and hyaline tube casts. The sputum usually contains not only the influenza bacillus but also the pneumococcus, streptococcus, staphylococcus, and the *Micrococcus catarrhalis*. The leucocyte count usually shows a moderate leucopenia.

Severe Influenza is characterized by an exaggeration of the symptoms and signs of ordinary influenza, and complications were frequent.

The following incident illustrates the onset: Two well developed unusually strong coal-passers were in the best of health on a Thursday, and when admitted to the U. S. Naval Hospital, League Island, the following morning were so weak that one fell on the floor and the other had scarcely sufficient strength to remain sitting on a chair.

The lips, lobes of the ears, and finger-nails shows cyanosis, varying in degrees from blueness to blue-

black, and occasionally extends to the extremities, trunk, and the mucous membranes of the pharynx and larynx.

In many cases adynamia is so profound that normal breathing was impossible. When the patient is commanded to take a deep breath he makes an obvious effort and breathes slightly more deeply, but each succeeding breath is weaker than its predecessor, evidencing weakness and rapid exhaustion. It is probable that feeble or absent breath sounds, when no pulmonary disease exists excepting a moderate bronchitis, is in part due to the excessive weakness of the intercostal muscles and diaphragm dependent upon deficient innervation and toxic myositis. Occasionally breath sounds were masked by numerous, loud, sibilant, sonorous, and mucous rales. Auscultation in bronchitis reveals an extremely weak respiratory murmur, and in many cases the breath sounds in one or both of the lower lobes are absent. Vocal fremitus and resonance are diminished, and bronchitis rales are few and scattered.

Lobular pneumonia is very common and usually begins in small areas disseminated throughout one or both lungs, frequently locating in the lower spinal half or the apex of one of the lower lobes, and usually undiagnosable at first because of the feeble or absent breath sounds, extreme engorgement and emphysema. During ordinary respiration subcrepitant rales may be absent but may be induced by cough or deep inspiration. These rales are easily overlooked because of their small volume and low pitch or may be masked by loud dry rales. Even when small areas of lobular pneumonia become larger, the phonendoscope reveals scarcely audible, low-pitched, bronchovesicular breathing, and percussion dulness may be absent if these areas are located in the central portion of the lung, or the surrounding tissue is emphysematous. When areas of lobular pneumonia coalesce and occupy the periphery or a considerable part or the whole of a lobe of a lung, the percussion note is dull, the breath sound bronchovesicular or bronchial and vocal resonance and fremitus are increased. Respiration is superficial in all forms of this disease, but in severe influenza the respiratory murmur is not only feeble but remains feeble even though one or both lower lobes of the lungs become congested or pneumonic. The unaffected showed no compensatory overaction, so uniformly observed in lobular pneumonia. Passive venous congestion of the base of the lungs is common. Occasionally dulness on percussion and feeble breathing leading to the diagnosis of bronchopneumonia will vanish over night, due to the disappearance of pulmonary congestion and collapse following the expulsion of a plug of tenacious mucopus blocking one of the larger bronchial tubes. The cough was frequent, paroxysmal and often interfered with sleep. The sputum was at first mucoid and later mucopurulent, moderate in amount, and frequently blood stained. The bloody sputum was usually at first bright red and later dark brown and occasionally salmon colored or rusty. When the sputum was thin and watery, resembling diluted red paint, the *Streptococcus hemolyticus* was usually present and death usually ensued.

In mild and moderate influenza the respiratory rate was ordinarily normal. Whenever the respirations exceeded 24 per minute, pneumonia was suspected and this suspicion was strengthened if the sputum was blood stained, excepting when pleuritis caused the increased respiratory rate. Polymorphonuclear leucocytosis usually accompanied bronchopeumonia. The combination of normal percussion resonance, vocal fremitus, and resonance with absence of breath sounds occurred so frequently that at first the author believed that his hearing was impaired or that the stethoscope or phonendoscope was defective, but repeated observations corroborated the first observation and in describing this frequently recurrent group of signs the term "silent lungs" was employed. In the beginning it was difficult to ascertain the causes of these "silent lungs," but soon the following were recognized:

(1) The lung failed to functionate because of adynamia and extreme weakness of the muscles of respiration.

(2) Extreme pulmonary engorgement.

(3) Obstruction of the lumen of the bronchial tubes by (*a*) inflammatory swelling of the mucosa; (*b*) tenacious and mucopurulent or hemorrhagic exudate.

(4) Collapse and congestion of an area of the lung, secondary to complete obstruction of the bronchus.

(5) Areas of lobular pneumonia surrounded by emphysema. Lobular pneumonia frequently exists unrecognized, or may later develop in condition described under 1, 2, 3, and 4.

Pleurisy almost always occurs as a complication of influenzal bronchopneumonia; it may be serous, serofibrinous, or purulent, frequently occurs in the absence of physical signs and symptoms, and may be general, interlobar, or diaphragmatic.

The characteristic superficial friction rub was usually inaudible because of feeble respiration or because the exudate was butter-like in consistency. A crumpling or subcrepitant-like sound occurring at intervals during the early part of the inspiratory phase of respiration, simulating the crepitant rale of pneumonia or the subcrepitant rale of capillary bronchitis, at times replaces the characteristic friction rub. Pleural friction sounds may be masked by loud bronchitic rales. Frequently pleural friction crepitant and subcrepitant rales were simultaneously present. Large serous effusion seldom occurred. In a few cases the quantity of soft gelatinous exudate was so large that the physical signs simulated that of a serous effusion, but the aspirating needle revealed no fluid. In many cases the pleuritis remained plastic throughout, but was usually accompanied by a serous exudate small in amount, light brown in color, of high specific gravity, markedly albuminous and occasionally contained the pneumococcus or streptococcus. Serous exudate usually occurred without recognizable symptoms, but if not too small in amount was easily diagnosed by physical examination. In many cases of pleurisy the severe pain caused diminished pulmonary expansion, feeble breath sounds, and an increased rate of respiration, and these same signs were occasionally observed in plastic pleurisy without pain, probably due to reflex action. Reflex pleuritic pains have been erroneously diagnosed as cholecystitis or ap-

pendicitis. Physical signs of a large serous effusion appeared over night in a few cases of bronchopneumonia without causing a marked increase in dysponea, polypnea, or displacement of the apex beat of the heart. This combination of signs and symptoms led to the inference that although the physical signs indicated a large effusion, the absence of pressure signs was best explained by assuming that the effusion was moderate in amount and was located between layers of the pleura, having a thickness of about two inches, held in position by a non-collapsible bronchopneunomic lung. This clinical interpretation was confirmed later by a case that came to autopsy. In one case 200 cc of serous exudate were removed and a small pyopneumothorax developed as the bronchopneumonic lung could not expand. As a rule pleural exudates were absorbed, and when respiration was embarrassed, paracentesis was not performed. At short intervals a small quantity of the liquid was removed to determine whether it remained serous or had become purulent. Extensive adhesions are common after pleurisy and frequently the *x*-ray reveals complete adhesion of the lung to the diaphragm. Usually interlobar and diaphragmatic seroplastic and purulent pleurisy are not diagnosed but the latter may be suspected when friction sounds are heard over the borders of the lung or when referred pain occurs in the upper abdominal, gall-bladder, or appendix regions, or when the fluoroscope shows adhesions. Circumscribed, interlobar, or diaphragmatic pleural effusions are usually overlooked but should be diagnosed by the aspirating needle, physical signs, pain in the upper abdominal appendix region, and the *x*-ray. Pyothorax was diagnosed with difficulty excepting when the amount of pus was large. Sacculated, interlobar, and diaphragmatic empyema sometimes evades diagnosis and may be revealed by the sudden discharge through the lung of a pint or more of pus. After spontaneous rupture of an empyema into the lung the signs of pyopneumothorax often developed and recovery usually followed, but occasional drainage through the chest wall became necessary. Circumscribed interlobar empyema is more apt to evacuate through the lung than any other variety. In one case, following a severe paroxysm of cough an emphysematous bleb over an area of bronchopneumonic lung ruptured into the pleural cavity, infected the pleura, and caused a pyopneumothorax. In one case two sacculated empyemas were observed in one pleural sac.

During the epidemic of pneumonia occurring in the U. S. Naval Hospitals of Philadelphia in the Winter of 1917 empyema occurred in 25 per cent. of the cases, consequently this complication was expected in this epidemic. Contrary to this expectation, however, empyema was of rare occurrence during the height of the epidemic and relatively few cases occurred later. When empyema appeared, the streptococcus or pneumococcus was usually present. Antistreptococcus serum was of unquestioned value in influenzal streptococcus empyema, and one case of influenza complicated by pneumonia followed by empyema, due to pneumococcus type I, was greatly benefited by antipneumococcus serum, injected subcutaneously and also into the empyema cavity which had been partially evacuated by paracentesis.

In severe influenza circulatory disorders were almost as common as pulmonary disorders. Weakness of the heart muscles was usually present in varying degrees, and in most cases the muscular element of the first sound was remarkably weak and at times valve-like. Frequently the apex beat could not be seen or felt. The cardiac neuromuscular mechanism was usually disturbed, as shown by the frequency of the alteration in the pulse temperature ratio, as for example, temperature 104 deg. F., pulse 80. As a rule the pulse was hypotensive and weak but regular in force and rhytnm. Occasionally the cardiac rhythm was transitorily disturbed during a paroxysm of cough or by exertion. Arrhythmia from neuromyocardial disease was rare, and in one case sudden and unexpected death occurred. The systolic and diastolic pressure was low, the pulse pressure large, and in a typical case the systolic pressure was 85 mm. and the diastolic 45 mm. The frequency of this blood-pressure picture in association with marked adynamia closely simulated that of advanced Addison's disease and suggests a diminution or loss of function of the adrenals. Although cardiac murmurs were usually absent, nevertheless it is possible that in certain cases, sufficient ventricular dilatation occurred to permit of tricuspid or mitral regurgitation, the absence of the murmur being due to myocardial weakness.

Pericarditis was conspicuous by its absence and hydropericardium was only occasionally observed. The superficial and deep veins were frequently overdistended, and the arteries seemed less full than normal, indicating a partial emptying of the arterial blood into the venous system.

Cyanosis was a frequent, striking, and serious complication of the epidemic. In mild cases the lips, ears, and finger-nails were slightly bluish; in ordinary cases the cyanosis of the lips and ears increased and also extended to the cheeks and hands; the color became more distinctly blue. In severe toxic influenza cyanosis may extend all over the entire body and include the mucous membrane of the mouth, and the color may deepen to a bluish black. All the factors concerned with the cause of cyanosis could not be fully determined, but it was evident that the chief and perhaps the sole cause was a toxemia acting upon various organs and tissues of the body. There was evidently a disturbance of the function of the vasomotor mechanism and a diminution or loss of the function of the adrenals due to inflammation.

Toxic myocarditis caused pulmonary and venous congestion which was increased by the partial emptying of the arterial blood into the venous system, which with toxic bronchopneumonia favors suboxidation of the blood. Digitalis, atropine, and alcohol usually failed to produce their physiologic effect and venesection was useless or harmful.

In the nervous form of severe influenza, the mind was usually dull, somnolence was common, and the patient slept most of the time but was easily awakened. When toxemia was more marked somnolency was replaced by slight, moderate, or marked stupor or coma. Delirium might occur similar to that seen in typhoid fever, or might become maniacal and require physical restraint. In a few cases delirium continued for days accompanied by photophobia and

slight retraction of the head, simulating meningitis, evidently due to a toxic irritation of the meninges and cerebral cortex as the spinal fluid showed no evidence of inflammation. Frequently lethargic or mildly stuporous patients with extensive bronchopneumonia, obviously critically ill and within 24 to 48 hours of death, nevertheless stated that they felt well and requested permission to leave the bed and return to duty. This strange inability to appreciate the seriousness of their condition was probably due to a marked disturbance of the perceptive centers. Marked mental depression was not uncommon and was sometimes associated with the fixed idea that recovery was impossible and that death must follow.

Delusional insanity of the mild, melancholic, or suicidal variety occasionally occurred. A convalescent from influenza while working about the hospital wards, apparently improving, was suddenly seized with a suicidal impulse, secured a razor and cut his throat, but fortunately recovered; a second patient was foiled in an attempt to commit suicide by jumping from a height, and a third patient had a series of epileptiform convulsions preceded and followed by melancholic or depressive delusions from which he ultimately recovered. Adynamia was marked and the decubitus indicated extreme muscular relaxation. Involuntary evacuation of the urine and feces was common, and the patient might unconsciously expectorate anywhere at any time.

In the gastrointestinal form of influenza the most common symptoms are a coated tongue, foul breath, aversion to foods and drinks, unwillingness to swallow, anorexia, nausea, and vomiting. The vomitus is usually free from blood, the abdomen may or may not be tympanitic and is not painful upon palpation. Blood appeared in the feces of three cases of influenza, one of which was complicated by typhoid fever. Diarrhea occasionally occurred when there was no evidence of gastroenteritis now ulceration and it was evident that toxemia was the chief factor. This form of influenza was frequently fatal.

The renal form occurred in three-fourths of the cases of severe influenza. The urine usually showed a trace or a moderate amount of albumin, a high specific gravity, granular and hyaline tube casts, and not infrequently a number of erythrocytes, interpreted as indicating acute toxic nephritis. The volume of urine excreted was usually diminished, and clinically it was impossible to recognize evidences of uremia which, if present were merged into the clinical picture of toxemia. In a few instances the phenolsulphonephthalein test for the functional activity of the kidneys was made, but the results were so contradictory that deductions were impossible. One would expect varying degrees of diminution of the renal function, and in severe toxemia the renal function should be almost abolished. Passive congestion of the kidneys was common.

Jaundice occurred infrequently and was due to toxic hepatitis and no case of catarrhal hepatitis or cholecystitis was observed. Several cases of severe pain referred to the gall-bladder region, due to pleurisy were diagnosed cholecystitis. In one case, a negro, the jaundice was so intense that the sputum was canary yellow in color due to bile. About half of the cases of jaundice terminated fatally. Primary sinusitis and otitis were rare, but occasionally latent sinusitis and otitis became acute during influenza. Paracentesis in acute otitis media usually yielded a bloody serum, but seldom pus. Epistaxis was very common and was usually associated with venous engorgement and passive swelling without evidence of inflammation. The blood seemed to ooze from the mucous membrane and usually no ulceration could be detected.

Hoarseness and aphonia occasionally occurred, and the laryngoscope showed passive congestion and swelling.

Commander W. A. Angwin, M. C., U. S. N. has made the following statistical study of nine hundred cases admitted and discharged from the U. S. Naval Hospital between September 12 and November 15, 1918. Group 1 consists of 352 cases admitted within 24 hours of onset. Group 2 consists of 197 cases admitted within 48 hours of onset. Group 3 consists of 116 cases admitted within 72 hours of onset. Group 4 consists of 235 cases admitted after 72 hours of onset.

The symptoms in the order of frequency were headache, cough, general muscular pains, chills, backache, weakness, sore throat, coryza, nausea, dyspnea, vertigo, vomiting, earache. The physical signs in the order of frequency in group were: rales 51.9 per cent., congestion of the throat, eyes, and nose, cyanosis, toxemia. enlargement of the superficial lymphatic glands, pleuritic friction, herpes, and erythema. Rales, toxemia, and delirium progressively and rapidly increased in frequency from group one to group four. Delirium occurred in 48.6 per cent. of all cases of pneumonia.

Complications and Sequelæ: Toxemia dominates the clinical picture of influenza and is not only the chief complication but also the chief cause of death. Young men possessed of unusual strength and vitality succumb without resistance due to the virulency of the toxemia.

The usual pulmonary, circulatory, nervous, gastrointestinal, and renal complications and cyanosis have all been sufficiently discussed. Hypostasis with pulmonary edema is a frequently fatal terminal complication of pneumonia. Uncommon complications are phlebitis, thrombosis, neuritis, parotitis, sinusitis, aphonia, herpes, purpura, and subcutaneous emphysemo. Relapses are not uncommon but many so-called relapses occurring in convalescents are due to

the recrudescence of existing bronchitis, pneumonia, or pleurisy or the conversion of a serous into a purulent pleural effusion. Any preexisting disease, as for example, pulmonary tuberculosis or chronic Bright's disease, may become a serious or fatal complication or sequel by becoming active and progressive during an attack of influenza. Five cases of influenza were complicated by meningococcic cerebrospinal meningitis. One case of influenza developed diphtheria and bronchopneumonia involving the middle and lower lobe of the lung, and another typhoid fever, and it is probable that all were carriers. Many carriers of the pneumococcus, streptococcus, or staphylococcus became infected with the influenza bacillus. Influenza occurring in carriers of various microorganisms is the cause of many obvious or obscure complications.

The most common sequel of influenza is well marked weakness, continuing many weeks, due to the effect of the toxemia upon the nervous system or myocardium causing well marked symptoms of neurasthenia, circulatory weakness, anginoid pain, or angina pectoris, or the weakness may be circulatory and myocardial in origin.

Chronic bronchitis, chronic pleuritis, empyema (sacculated or general), pyopneumothorax, emphysema, chronic bronchopneumonia, chronic sinusitis, chronic otitis, may occur as complications or sequelæ.

A large number of influenza carriers may be expected as a sequel to this pandemic, as the sputum in 36 per cent. of the patients convalescent for two or three weeks still contained the influenza bacillus.

Pathology and Clinical Laboratory: I am indebted to Lieutenant R. S. Leopold, M. C., U. S. N. R. F., not only for the statistical tables, necropsy, pathological and clinical reports, but more especially for his enthusiastic cooperation during the epidemic.

The blood in influenza usually showed leukopenia and the white blood cells varied between 3,800 and 8,000 per c.mm. As soon as pneumonia occurred, a polymorphonuclear leucocytosis quickly developed, varying from 14,000 to 20,000 per c.mm. Leucocytosis usually antedated the clinical diagnosis by two or three days. When leucocytosis diminished during the active stage of influenzal bronchopneumonia the prognosis was generally unfavorable.

The following table has been constructed by selecting from 600 blood counts, 100 from uncomplicated pneumonia and 100 from influenzal bronchopneumonia:

	W.B.C.	Polys.	S.L.	L.L.	Mono.	Trans.	Eos.
Influenza	6.950	67.5	21.2	3.8	4.4	2.1	0.2
Influenzal broncho-pneumonia	17,680	82.8	8.3	2.1	2.6	3.8	0.1

The following table is based upon 200 examinations of sputum selected from 600 cases of influenza between Sept. 28 and Oct. 28, 1918:

	Per Cent
1. *B. influenzæ* (pure)	18
2. *B. influenzæ* and streptococci	14
3. *B. influenzæ* and pneumococci	12
4. *B. influenzæ*, streptococci and pneumococci	12
5. Pneumococci	10
6. Streptococci	10
7. Pneumococci and streptococci	18
8. Total *B. influenzæ* present	62

In the sputum of patients convalescent two or three weeks *B. influenzæ* was still present in appreciable numbers in 36 per cent. of the cases examined, thus demonstrating the probability of a high percentage of carriers.

The *B. influenzæ* was at first identified with difficulty and later with regularity and ease owing to improved technique. This organism was frequently associated with type III and IV pneumococcus, occasionally with type II and only rarely with type I. Streptococci of varying strain and virulency were associated with *B. influenzæ*, and occasionally the *Streptococcus hemolyticus* was identified and less frequently the *Micrococcus catarrhalis* and staphylococcus. In fifteen blood cultures twelve were negative, one showed a pneumococcus, and one a pneumococcus and streptococcus. When the influenza bacillus and the streptococcus or pneumococcus were simultaneously cultured on the same plate, the colonies grew larger and more rapidly than if each organism were grown upon a separate plate, this being evidently due to symbiosis.

Spirilla, not of the mouth variety, were frequently observed in the sputum, especially when bloody, from patients with influenza. The morphology of the organism was constant, it was relatively short, the ends curved, convolutions regular and about six or eight in number, and stained faintly with strong fuchsin. These organisms were imbedded in mucopus which had apparently come from the lower respiratory tract and were observed in 14 cases of influenza and 9 cases of bronchopneumonia. The giving of 0.2 to 0.4 grams of salvarsan caused the disappearance of the spirilla and apparently benefited the patient. Future research must determine the relation of this organism to influenza.

Dr. Leopold has made the important observation that from material obtained by an aspirating needle introduced into a bronchopneumonic area, a pure culture of the bacilli was obtained, and that other organisms might be secured from areas surrounding the consolidation or from the content of the bronchial tubes.

The relative frequency of the different types of pneumococci were as follows: Type I, 1.1 per cent.; Type II, 12.3 per cent.; Type II, *a*, 14.6 per cent.; Type III, 5.6 per cent.; Type IV, 25.6 per cent.; Negative, 40.6 per cent. In other parts of the United States the percentage of the different types varied.

A composite picture of nine autopsies would be about as follows: A robust, well-developed, muscular young male cadaver, presenting extreme cyanosis of the entire body, often of a deep purplish black and emitting a characteristic foul odor. The engorgement of the venous system was extreme and the subcutaneous and abdominal veins and cavæ were greatly overdistended, and the blood which flowed freely was black in color, watery in consistency, and produced a dark mahogany-colored stain. The right heart was enormously overdistended and filled with a blackish jelly-like clot.

The heart, pectoral, and abdominal recti muscles were all well developed and often presented a glazed and scalded appearance. The heart-muscle fiber stained faintly, and the individual cell was swollen and faintly granular, the nucleus clouded,

and the capsule indistinct. Between the bundles of the heart muscle fibres there was congestion, occasional minute hemorrhages, groups of infiltrated round cells, and small collections of leucocytes. The intima of certain of the cardiac arterioles showed marked proliferation sufficient partially to obstruct the lumen of the vessels.

An occasional serous pleural effusion and a few examples of seropurulent pleuritis were observed late in the epidemic.

The lungs presented constantly varying pictures of bronchopneumonia. The discreet areas of lobular pneumonia presented various stages of development and some were well defined, elevated, firm, varying in color from a reddish brown to bluish gray and surrounded by normal or collapsed lobules, giving a mosaic appearance. The areas of lobular pneumonia were often scattered throughout the middle and lower lobes and sometimes also appeared in the upper lobes, often involving from 25 to 50 per cent. of the lungs. In other cases these areas rapidly coalesced, became massive and simulated lobar pneumonia. These massive pneumonias often involved 75 per cent. of the lung and were of a bluish gray color, were occasionally associated with subpleural hemorrhages.

Bronchopneumonia invaded the lung in the following order of frequency: the right lower lobe, the left lower lobe, the middle lobe. In all types of pneumonia areas of extreme emphysema were observed, especially marked in the uninvolved lung. In one case of pyopneumothorax developed secondary to the rupture of an emphysematous bleb over an area of bronchopneumonia.

The trachea and bronchi contained a thin brownish tenacious exudate and numerous minute petechial hemorrhages were common in and apparently under the mucosa.

Frequently the interlobar capillaries were intensely congested with areas of hemorrhagic extravasations. The alveoli were filled with red cells, leucocytes, fixed cells, debris but no fibrin. Peribronchial and perivascular round-celled infiltration was especially pronounced in the broncho-pneumonic areas. Enlarged bronchial glands were often found about the roots of the lungs.

Only a few examples of aerofibrinous or purulent pleuritis were observed.

The Influenza Committee of the Advisory Board of the D. S. M. S., France, reports in the *British Medical Journal* of November 9, 1918, that one of the most striking features of the morbid anatomy of the epidemic was the constant occurrence of dilatation of the heart with myocardial changes. Twenty-nine out of thirty cases showed marked dilatation of the heart, chiefly of the right side, but very commonly of the left side as well, twenty-one cases showed myocarditis demonstrable to the naked eye. The myocardium was pallid and soft with mottling and frequently subpericardial and subendocardial hemorrhages similar to those seen beneath the pleura. These hemorrhages were also seen on the intraventricular septum and papillary muscles.

The pericardium usually showed no pathological change and only occasionally was a moderate serous effusion observed. In a typical rapidly fatal case of toxic influenza, with bronchopneumonia and extreme cyanosis, the venous system was engorged with blood, the lumen of the divided ascending and descending venæ-cavæ were distended to fully one-third larger than normal and filled with a currant jelly-like clot. When blood was removed from the pericardial sac, it quickly refilled with blood regurgitation from the over-full venæ-cavæ.

The gastrointestinal tract showed no pronounced pathological change.

The spleen was usually somewhat enlarged, congested, and of a deep purplish color. The liver was congested and sometimes showed marked biliary pigmentation.

The kidneys were congested, the cortex was usually deep brown in color and upon section showed a glazed and bulging surface. The microscope showed uniformly advanced inflammatory changes with extreme congestion; the capillaries seemed almost ready to burst and hemorrhages were frequently observed. In and around of the lobular and interlobular vessels there was advanced cloudy swelling, especially of the convoluted tubules, and in some cases inflammatory changes were taking place in the glomerotubular portion of the kidney.

The adrenals were of a deep bronze color, enlarged, very friable, and extremely congested.

Major O. L. Pothier, M. C., U. S. A., Camp Lee, Virginia, in a report upon thirty-seven autopsies, states that during the first week of the epidemic the adrenals were intensely congested with beginning change in the epithelial tissue; but after the second week the cellular element had disappeared leaving only a framework. He states that with the exception of the lungs no other internal organ suffered as much as did the adrenals.

If autopsies had been more numerous and research more exhaustive, doubtless evidence of toxic hepatitis, splenitis, and pancreatitis would have been observed and possibly similar changes in other organs.

Diagnosis: The diagnosis of influenza during an epidemic is based upon fever with a disproportionately slow pulse and respiration rate, pain in the head and extremities, flushed cheeks, bright eyes, injected conjunctivæ, cough, quickly accompanied by mucopurulent expectoration. As a rule sneezing is absent and when present is apt to be due to an associated *Micrococcus catarrhalis* infection. The pulse and the muscular element of the first sound of the heart quickly become weak. The temperature is usually about 103 deg. F., and the pulse only 100 per minute. Frequently bronchopneumonia exists with a respiratory rate of but 26 per minute.

A primary lobar pneumonia may be mistaken for a massive influenzal bronchopneumonia. The differential diagnosis is established by the character of the pulse and the first sound of the heart, the relative slow pulse and respirations and the association of bronchitis or lobular pneumonia in other lobes of the lungs. It is evident that in a few cases the pneumococcic infection was as great as, if not greater than the primary influenzal infection, because of the rapid consolidation of one or more lobes of the lung and a typical crisis at the usual time. The diagnosis of other pulmonary, pleural, and circulatory diseases in severe toxic influenza has already been discussed.

Leucopenia is diagnostic of uncomplicated in-

fluenza, and polymorphonuclear lucocytosis appears when pneumonia occurs and may antedate the clinical diagnosis by two or three days. Material for culture secured by introducing an aspirating needle into an area of bronchopneumonia makes an etiological diagnosis possible.

Prognosis: The estimated death rate at the U. S. Naval Hospital was 11.6 per cent. The actual mortality was lower, as patients recovering, while on leave, were not included.

About one-third of the cases of severe toxic influenzal bronchopneumonia and most of the cases of influenza with involvement of both lower lobes of the lung, succumb to the disease. When the sputum appears like diluted red ink, denoting infection by the *Streptococcus hemolyticus*, death usually occurs. Well-marked stupor or persistent vomiting is unfavorable prognostically. Sudden death may occasionally occur in influenza when arrhythmia is present. In a few instances the usual clinical evidences of severe toxemia make the prognosis unfavorable even though bronchopneumonia be absent.

Occasionally acute tonsillitis is erroneously diagnosed influenza, but inspection of the fauces and a study of the pulse, temperature, respiration and leucocyte count makes the differentiation. ,

Practically all toxic psychoses improved and eventually recovered. Acute parenchymatous nephritis usually disappeared but occasionally became chronic. When a patient with influenza continues at work the prognosis is unfavorable. Dr. J. J. Reilly, Chief Surgeon at Hog Island, states that two men with influenza, while at work, were accidentally killed and an autopsy showed bronchopneumonia.

Summary: This epidemic was introduced into the United States by ships from abroad; it differed markedly from preceding epidemics and was characterized by rapid and severe onset, extreme contagiousness, and high death rate.

The period of incubation was one to four days.

The epidemic disappeared because most of the nonimmunes had been infected.

Extreme susceptibility of the young adult and comparative insusceptibility of those past middle age were characteristic.

Non-resistance to the disease, even by those of unusual strength and vigor, were noted.

Toxemia was the dominant cause of symptoms, complications, and death by direct action upon the tissues and organs of the body.

Cyanosis occurred frequently, and if extensive, was serious prognostically.

The chief and perhaps the sole underlying cause of cyanosis is toxemia. Some of the secondary causes of cyanosis are disturbance of the vasomotor system, toxic myocarditis, bronchopneumonia and congestion, with over-full venous system, epinephritis, and suboxidation of the blood.

Hypoadrenalism was suggested because of the frequency of low systolic and diastolic and large pulse pressures with adynamia. In a series of thirty-seven autopsies many showed marked disease of the adrenals. This shows the importance of an exhaustive study of the adrenals in future epidemics of influenza.

Adynamia is probably due to the effects of the toxemia upon the nervous and muscular systems and the adrenals.

Deficient pulmonary expansion is often due to toxemia affecting the muscles and nerves concerned with respiration.

The most common location of a beginning bronchopneumonia is in the apex of the spinal half of the lower lobe of the lung.

Bronchopneumonia may exist in the absence of breath sounds, due to nonentrance of air, and percussion resonance may be normal due to associated emphysema.

The appearance of the *Streptococcus hemolyticus* in the sputum in influenza bronchopneumonia is usually followed by death.

Absence of compensatory overaction of the normal lung when massive bronchopneumonia exists is an indication of a disturbance of the neuromuscular mechanism due to toxemia.

Pleural friction frequently closely simulates the crepitant and subcrepitant rales of bronchopneumonia.

Empyema was infrequent during this epidemic but was common during the epidemic of pneumonia in Philadelphia in the Winter of 1917.

Referred pleuritic pain is often mistaken for cholecystitis or appendicitis.

Feeble or absent apex beat, weakened muscular element of the first sound, relatively slow pulse as compared with the fever are evidences of myocardial change or toxic myocarditis.

Frequency of toxic myocarditis at autopsy as observed by the Influenza Committee of the Advisory Board, D. S. M. S., France.

Meningismus was frequently mistaken for meningitis.

The prognosis was usually favorable in post-influenzal delirium and delusional insanity.

The prognosis was unfavorable when vomiting was persistent.

About three-fourths of the cases of severe toxic influenza developed catarrhal nephritis.

Leucopenia is diagnostic of uncomplicated influenza. Polymorphonuclear leucocytosis is diagnostic of bronchopneumonia and may antedate the clinical diagnosis by two or more days.

The prognosis is unfavorable when influenza occurs in a pneumococcus streptococcus, staphylococcus, meningococcus, tuberculosis, or typhoid carrier.

It is probable that this epidemic has created a large number of influenza carriers. The sputum of 36 per cent. of patients convalescent for two or three weeks contained the *B. influenzæ*.

B. Influenzæ alone or combined with other organisms occurred in 62 per cent. of the sputa examined.

The frequent occurrence of pure culture of *B. influenzæ* from the diagnostic puncture of the bronchopneumonic areas of the lung was noted.

The rarity of Type I pneumococcus and its greater frequency in other parts of the United States were noted.

There was an evident symbiotic relationship of *B. influenzæ* to the streptococcus or pneumococcus and perhaps other microorganisms.

Spirilla were frequently observed in influenzal bronchopneumonia, especially when the sputum was bloody.

This epidemic of influenza seems to have been primarily due to the *B. influenzæ* which may have

been of the pandemic strain possessing unusual virulency. This influenza bacillus not only lessens remarkably the resistance but also greatly increases the susceptibility of patients with influenza to infection by other microorganisms. Many patients with influenza were quickly invaded by varying strains of the pneumococcus and streptococcus of high virulency. When an infection of two or more microorganisms occurred it seemed as though each stimulated the other to more rapid growth and greater virulency. Perhaps the symbiotic relationship of the influenza bacillus to the pneumococcus or streptococcus seen in the laboratory may also occur in the human laboratory. Spirilla so frequently observed in this epidemic may possess an importance now unrecognized.

The epidemic of pneumonia in the winter of 1917 produced a large number of carriers, which may partly explain the frequency of pneumonia complicating influenza. The importance of carriers in explaining certain aspects of this epidemic is illustrated by the occurrence of influenza in five meningococcus carriers each of whom quickly developed the symptoms of epidemic cerebrospinal meningitis. Some authors believe that an unknown microorganism or virus caused this epidemic.

317 South Eighteenth Street.

THE DISPENSARY SITUATION IN NEW YORK CITY.*

By E. H. LEWINSKI-CORWIN, Ph.D.,

NEW YORK.

EXECUTIVE SECRETARY OF THE PUBLIC HEALTH COMMITTEE OF THE NEW YORK ACADEMY OF MEDICINE.

When the Radicals in the French Constituent Assembly of 1848 were attempting to put every possible safeguard into the Constitution and the document grew to be huge, the poet-statesman Lamartine, who presided over the Assembly, remarked "Gentlemen, let us leave something to Providence."

In attempting to condense the findings of a year's investigation of the dispensary conditions in this city and the recommendations of the Public Health Committee based on these findings, within the compass of a short paper, I had constantly to keep in mind Lamartine's injunction, lest the paper become a jejune catalogue of subjects.

On behalf of the Committee, I desire to express sincere appreciation of the courtesy and cooperation shown by the authorities of the 45 institutions included in the survey, to the many individuals who gave us their helpful assistance and advice in connection with the study, to the Bureau of Municipal Research, which contributed the valuable services of Dr. Carl E. McCombs for several months, to the members of our staff, particularly to Dr. Anna M. Richardson, Dr. Gertrude E. Sturges, Miss Mary R. Foley, Miss Grethe Kjoss, Miss Amelia Massapust and Mr. Richard Mackenzie, who most efficiently and devotedly gave their services to the work, and to the Rockefeller Foundation for the generous appropriation which made this study possible.

*A Report on the Results of a Year's Investigation and Study by the Public Health Committee of the New York Academy of Medicine, presented at a meeting of the New York Academy of Medicine on December 18, 1919.

I. Magnitude of the Dispensary Problem.—Aside from any other consideration, the very magnitude of the dispensary field in New York City justifies a thorough inquiry into the numerous medical, social and economic problems which it raises. We have in Greater New York 65 Out-Patient Departments of Hospitals, 34 Independent Dispensaries and 6 College Dispensaries. In addition, the Health Department maintains 21 tuberculosis clinics, 8 dental, 10 eye and 3 rabies clinics, and the Children's Aid Society maintains 6 school dental clinics, making a total of 153 licensed dispensaries in New York City. In this list are not included the 3 occupational clinics, the 12 venereal disease clinics of the Health Department (all but 2 of which are Advisory Clinics) and 60 baby health stations.

The total number of treatments given at the 153 licensed dispensaries for which statistics are published by the State Board of Charities reaches the stupendous figures of over 4 million annually.

The total number of persons treated is reported as one and a quarter million. This figure is admittedly in excess of the actual number of persons using the dispensaries, because in the course of a year a large number of those seeking dispensary aid register more than once in the same institution for different ailments and some apply to more than one dispensary for the same complaint, and no method has been worked out whereby the actual number of individuals seeking dispensary treatment can be ascertained.

The clinics hold 3680 sessions weekly and the total number of hours of actual operation is almost 8000, thus making an average of over two hours per session. Most of the dispensaries are open during the morning and afternoon hours. The number of dispensaries open in the late afternoon hours is relatively small and the total number of evening clinic hours amounts to 213½ or a little over 2.5 per cent. of the total number of clinic hours per week.

Of the aggregate number of almost 8000 physicians in this city, 2019 are connected with dispensary work. 68.6 per cent. of these are associated with out-patient departments of hospitals and 31.4 per cent. with independent dispensaries. 1580 or 78.3 per cent. of the physicians hold one dispensary service, 366 or 18.1 per cent. two dispensary services and 73 or 3.6 per cent. three dispensary services.

In the vast majority of instances the services of dispensary physicians are not compensated.

According to the available statistics one-fifth of the patients is taken care of in the department of internal medicine, one-eighth in the department of surgery, one-ninth in the department of pediatrics and the remainder is distributed among the several specialties.

In other words, 80 per cent. of the dispensary patients come with complaints which are being taken care of in departments other than that of internal medicine. This is equivalent to saying that by a process of evolution conditioned by economic, medical, and public health forces, the dispensary has become an institution to which a large part of the wage-earning class of our population resorts when in need of services of specialists or of

a special examination or treatment, which in the majority of instances they cannot obtain except at the dispensary.

The recognition of this condition calls for a reconsideration of the whole dispensary problem from the standpoints of economics, administrative policy, and the relation of the medical profession to the dispensary.

II. The Dispensary Law.—According to the Rules of the State Board of Charities, all persons applying for advice or treatment at a dispensary must be questioned as to their ability to pay a physician, and only those who are, in the opinion of the registrar, unable to pay physicians or dentists, shall be accorded treatment. Exceptions to the rule are permitted in emergency cases and cases of communicable disease (this refers chiefly to tuberculosis and venereal diseases), and in cases applying at dispensaries connected with medical schools which may be "selected for use in clinical instruction." It is a misdemeanor to obtain medical or surgical treatment on false representation. The questioning concerning the financial status of dispensary applicants required by the rule just mentioned is more or less perfunctorily performed and although the law has been on the Statute Books for 20 years, not a single case has been brought to court.

Studies made at various times in several cities, including New York, show that the amount of imposition upon the practically free services of dispensaries is not flagrant and does not constitute an important factor in the dispensary problem. The study conducted by a Special Committee of the New York County Medical Society in 1912[1] led to the conclusion that 10 per cent. of the patients seemed "able to pay for medical treatment under ordinary circumstances, but the margin over and above fixed expenditures seemed in most cases so slight that in illness demanding continued treatment or the services of a specialist, to pay a physician would mean for them serious deprivation or the incurring of debt from which afterwards it would be difficult to escape."

A study of 1,000 cases at the Presbyterian Hospital Dispensary in Philadelphia showed that in 2 per cent. of the cases the acceptance of free care offered by the dispensary amounted to abuse.[2]

The Illinois State Health Insurance Commission reported in May, 1919, that according to their study 4.5 per cent. of the dispensary patients "were recipients of medical charity which their economic status did not justify."[3]

Similar studies at the Boston Dispensary and at the Washington University Dispensary at St. Louis led to the conclusion that 2 per cent. of the cases were taking undue advantage of the free services of the dispensary physicians.[4]

Our own study, based on first hand information obtained from the patients who were visited in their homes, corroborates the findings of the other investigations. We found that 2.2 per cent. of the patients were palpably taking undue advantage of the dispensaries, that 79.4 per cent. were justified in the use of dispensaries because of low economic status, and the rest, or about 19 per cent., because they sought the services of specialists or the use of equipment and apparatus which could not be obtained anywhere, except in a dispensary, at a price which they could afford to pay.

In view of this, the dispensaries may be said to have ceased to be institutions for the destitute only and have come to occupy a prominent place in the treatment of disease among wage-earners. This leads to the consideration of the question of prevailing fees and points to the need of pay clinics.

III. Fees.—The prevailing charges for admission, drugs, dressings, apparatus, and so on, vary from institution to institution. No effort has been made to standardize charges. They are invariably very low, although in some institutions the registration fee is as high as one dollar. Municipal hospitals have thus far refrained from charging any fees in their out-patient departments, although payments are accepted in such hospitals for the maintenance of ward patients. During the last year the charges in very many institutions have been slightly increased. The increase in charges leads at times to a falling off of the number of patients, who seek treatment in institutions where the charges are lower. There is an evident need of an equalization policy in the matter of charges for treatment, as well as for medicines, dressings, and apparatus, and an attempt along these lines should be made jointly by all the institutions, including the municipal.

At least three considerations must be borne in mind when the problem of fixing dispensary charges is undertaken. First, all the institutions are in need of additional income for the purpose of improving the services; second, the majority of the wage-earners are able to pay part of the cost for skilled medical services, and third, there exists a class of patients—chronic invalids and the unemployed—who will be deprived of treatment altogether if the admission fee is demanded in every case. The fees should likewise be low or remitted to patients in tuberculosis and other similar clinics to which the patients are required to come for sanitary supervision. It is therefore necessary to adopt a system of carefully graded fees with a maximum not to exceed 50 cents and to make that system uniform in the dispensaries throughout the city. The wage-earner in a more or less steady employment could pay a fee of 50 cents per visit without hardship. Moreover, considering the fact that the majority of patients come to the dispensary to seek the advice of specialists, the suggested increased fee would not be considered prohibitory to most of them. They are at present compelled to resort to the practically free services of the dispensary because they cannot meet the customary charges of specialists. The adoption of a 50-cent maximum fee would materially increase the present dispensary income and would aid toward making possible the necessary improvements in dispensary service. It would help the institutions to pay salaries to physicians and to employ larger clerical, nursing, and social service staffs to carry on more adequately the manifold functions of the dispensary and to meet its responsibilities toward the patients and the community.

The institutions which are poorly equipped, and which would be unable to render a superior grade of service, would lose many of their patients who, upon paying a higher fee, would be more discriminating, and in this way the inferior institutions would be gradually eliminated.

IV. Dispensary Policy and Executive Direction.—There exists no standard method of dispensary organization, either from the administrative or medical point of view. The dispensary has too often been treated as a Cinderella in the hospital household—neither sufficient funds nor sufficient thought have been given to its organization and work.

The problems encountered in dispensary administration are probably more complex and difficult than are the problems arising in the management of a hospital, yet the majority of institutions lack a definite policy with regard to dispensary work, and the administrative supervision is in too many instances purely perfunctory. Likewise, with the exception of independent dispensaries, there seldom is an executive officer of training and ability attached to the dispensary whose duty it is to give undivided attention to the study of its problems and the development of adequate administrative procedure.

There is a need in most of the institutions of a clearly defined policy and responsibility to be formulated by the Board of Trustees and to be supervised by a joint committee representing the Board of Trustees, as well as the Medical Board. Provision should also be made, at least in the large institutions, for a full-time executive who would carry out the policies of the Board of Trustees and devote his undivided thought and attention to the administration problems of the dispensary. Many of the existing administrative deficiencies would be obviated by the existence of well defined policies and by the fixing of responsibility for their enforcement upon specially designated full time executives.

V. Responsibilities of Dispensaries.—On the basis of a conservative estimate, the expenditures of the New York dispensaries amount to at least two million dollars per annum. Institutions expending such considerable sums of public funds have definite responsibilities. These responsibilities are toward the community who supports the institutions, as well as toward the patients who should be assured efficient medical treatment, and toward the physicians and other workers in the dispensary, who should be afforded opportunity for training and for advancement in recognition of their service. The responsibilities of the dispensaries have in many instances not been fully realized nor have their opportunities that lie in the fields of preventive medicine, as well as in the amelioration of social conditions been appreciated, although the possibilities along these lines were pointed out half a century ago.

In May, 1868, the New York *Evening Post* published an account of the dispensaries in New York City, giving a brief history of their development, management, and economic value, and concluded in the following manner: "The dispensaries do their greatest service in the prevention of disease. The patients they care for form but a small part of their annual reports; those they assist in escaping a long and lingering sickness are by far the greater part of the whole number treated. The promptness with which aid reaches the sick poor is the crowning glory of the system. Disease is treated in its incipient stages, and death held at bay beyond the threshold of many a crowded tenement, by the immediate attention patients are able to get through this system. . . . The dispensaries are Boards of Health in miniature, averting thousands of physical ills, quietly and unostentatiously, that could never be reached in any other way. They were organized to benefit the poor, but, like all successful efforts to improve the condition of a single class, it has been found that their blessings fall, in a different form, upon all other classes."

At the time this was written, there were in New York City but few dispensaries and their work in the field of disease prevention lay chiefly in vaccinations against smallpox. With the increased opportunities at command at the present time in the field of both preventive and curative medicine the responsibilities of the dispensaries have increased manifoldly. They can become institutions for efficient medical diagnosis and treatment, public health centers in their respective neighborhoods, and can afford valuable training facilities to physicians, nurses, social service, and other workers.

Thus far they have failed to develop to the fullest extent their medical and educational opportunities.

In this brief summary are outlined only a few of the possibilities of organization which in the judgment of the Public Health Committee would enhance the efficiency of the dispensary as an important medical and social agency in the community.

VI. Reduction in Waiting Time.—To begin with, the long periods which patients are made to wait prior to admission to the clinic must be reduced. This can be accomplished either by a system of appointments, the feasibility of which has been demonstrated by the American Red Cross Clinic for Children at La Havre, or by the principle of limitation of numbers being more generally adopted. Either of these procedures not only reduces the patient's waiting time, but what is perhaps more important, prevents the swamping of the clinic physicians with numbers of patients which they cannot possibly take care of adequately.

VII. Diagnostic Clinic.—Another present day dispensary practice, that of assignment of patients to the several departments by lay registrars on the basis of the complaint of the patient, must likewise be remedied.

It is suggested that with the exception of conditions where the diagnosis is obvious, such as simple wounds or fractures, or where the disease or complaint is trivial or transient, such as common colds, all new patients in need of a general examination should be referred to a diagnostic division and, after an examination, assigned for treatment to the appropriate departments.

The physicians in the several departments would serve in the diagnostic division on a rotation basis. In this way the patients would receive the benefit that accrues from medical team work and the physicians would have a much better opportunity for a complete study of patients than exists under the present form of organization. Consultants of broad experience and recognized ability should be associated with and should actively participate in the work of both diagnostic and therapeutic departments.

VIII. Equipment.—In order to make the services in dispensaries as attractive as possible for physicians, and in order that the patients may derive

the greatest benefit from medical skill, it is imperative that the dispensaries be equipped with all the modern facilities for diagnosis and treatment of disease. Very many institutions have meager laboratory and *x*-ray or fluoroscopic facilities. The hospital laboratories on which many of the out-patient departments have to depend are too overcrowded with work for hospital patients to assume all the burden that proper medical work in the dispensaries would impose upon them. In addition to the lack of adequate laboratory equipment, the dispensaries are seldom equipped with therapeutic workshops and facilities for hydro-, mechano,-thermo-, and electrotherapy.

IX. Remuneration of Dispensary Physicians.—Even if all the necessary physical facilities were provided in the dispensary, it would not attract physicians for continued and sustained application if there were no other benefits to be derived from dispensary practice. Remuneration, even though nominal, affords a stimulus to a more conscientious performance of work, and makes possible a better discipline in the institutions. But what is even more important for the efficiency of the service is a medical organization correlating the dispensary service with that of the hospital, such as is already in vogue in the best institutions and should be adopted by the others. The essential features of a correlated dispensary and hospital service are herewith suggested.

X. Correlation of Dispensary and Hospital Service.—The medical organization of out-patient departments which are connected with hospitals should be divided into two main branches corresponding to that of the hospital, namely, medical and surgical. The medical division of the hospital and that of the dispensary should be under one director. Likewise, the two surgical departments should have common direction. The specialties in each branch should be differentiated in accordance with the policy of the responsible director and in accordance with the best interests of the medical and administrative organization of each institution. The out-patient service should be graded. The appointment to the lowest grade in the out-patient department should be made on a probationary basis of three or six months, and after a successful trial the probationer should, upon the recommendation of the Chief of Clinic and with the approval of the Board of Trustess, be appointed a member of the dispensary staff in the lowest grade. Upon the completion of a period of satisfactory service he should be promoted to a higher grade and whenever the conditions warrant, should be made a member of the lowest grade of the visiting staff of the hospital. A rotating service for the junior members of the visiting staff of the hospital, allowing a combined service in the dispensary and in the hospital is beneficial to hospital and dispensary alike.

Whenever such an arrangement exists, it affords physicians a stimulus to enter dispensary service; it adds to the experience of physicians, many of whom, on account of the limited facilities of hospitals, do not get the benefit of hospital association except during the one or two years of internship, and it gives to the hospitals a broader opportunity of choice of the visiting staff. A universal adoption of such a plan would be welcomed by the profession, and it would obviate to some degree, perhaps, the necessity for paying salaries to dispensary physicians. The opportunity for promotion to hospital rank counts for more than a salary reward for a routine day-to-day drudgery without hope for promotion.

In detached or independent dispensaries, where such a plan of organization could not be effected, arrangements with medical schools for organizing post-graduate instruction could perhaps be made, in order that the whole field of clinic work of this city should be permeated with the spirit of research and teaching, and in order that all existing facilities should be put to the most useful purpose.

The study of medical records has revealed the fact that the special institutions devoted to the treatment of particular conditions are almost invariably superior in their work to the corresponding branches of the general dispensaries. It seems therefore important that in making plans for the development of New York as a great medical teaching and research center, that the facilities and clinical material of the special institutions should be correlated and utilized to the fullest extent.

XI. Medical Records.—Adequate medical records prepared in a certain standard way and *legibly* written are one of the prime essentials of conscientious performance of work and of a scientific utilization of the clinic material. Under existing conditions, where the physicians in the majority of instances are required to write histories in the rush of clinic work, and where there is no supervision over the keeping of such histories, and no scientific or administrative stimulus for keeping them, the medical histories in very many instances are little more than worthless. Often the essential findings of the physical examination and the ancillary laboratory tests, or the character and method of treatment, are not recorded.

The analysis of the thousands of medical records obtained from a large number of institutions, although inadequate as an exact portrayal of medical work, indicates, however, that in very many instances dispensary work is of a slipshod character.

General physical examinations were found to be recorded for less than one-fifth of all the cases examined. For certain conditions such a procedure is probably unnecessary. In many others, however, the failure to make an adequate general physical examination is a serious omission and indicates to what extent the dispensaries could be improved if their responsibilities as agencies for the prevention of incipient disease and the discovery of remedial defects were fully realized. Then, again, the fact that the number of diagnoses recorded on the medical histories exceeds the number of physical or local examinations and the number of laboratory tests would indicate that the diagnoses are often forced without sufficient warrant. Even in cases diagnosed as nephritis, for example, records indicate that urinalysis was made in only 66.7 per cent. of instances. Among the cases of syphilis studied, in only 50 per cent. was an indication found that the patient had been given proper treatment.

For the efficient functioning of the clinics it is desirable that Clinic Staff conferences should be held regularly and cases reviewed. The members of the staff should be urged to study intensively certain series of records and make analyses of them for presentation, discussion and publication.

XII. Clinic Secretaries.—Another important factor in increasing the efficiency of the clinic is the despatch with which patients are prepared for examination. There are few institutions in this city at which clinic secretaries, as they are called, are employed. Wherever the experiment has been tried, whether with paid or volunteer workers, it has proved to be of great value. It is very important that clinic secretaries be generally employed as adjuncts in the discharge of clinic procedure. Many volunteers could be secured for the service from among those in the schools for social service, for whom such an experience would be of invaluable assistance in their future careers. A certain number of paid secretaries will, under any conditions, be necessary in the clinics in order to train volunteers and facilitate the work of the physicians, and to spare the patients a great deal of waste of time and effort and also their occasional disappointment and discouragement.

XIII. Follow-up Service.—One of the tests of a dispensary's efficiency is the hold it exercises over its patients, for unless patients return for treatment until discharged a great deal of the effort and money expended has been lost. As matters stand, the return visits in some of the departments of the clinics are very few. In certain departments, like the tuberculosis, venereal disease and children's, efforts are being made to bring the patients back through the follow-up system, which in the majority of institutions consists in notifying patients who fail to come on an appointed day that they should return to the clinic. Only in certain institutions are the patients visited by the agents of the dispensary and urged to come back. There are very many reasons for the failure of the patients to return. They sometimes get discouraged, very frequently again, the symptoms which in the first instance drove them to the dispensary disappear, and it is not evident to them that they should continue treatment. In this study it has been shown that the majority of the patients gave "pain" as the chief symptom which prompted them to seek medical advice. It is essential for an efficient clinic to have an adequate number of workers who would be able to impress the patients with the importance of continuing treatment, even when the distressing or annoying symptoms disappear.

The number of cases of syphilis or gonorrhea which remain under treatment until discharged by the clinic is almost negligible, and no systematic efforts have been made to examine the families of the infected patients. In this respect the experience of tuberculosis clinics, where efforts in that direction have become a part of the routine of procedure, may be pointed out as a possibility for larger prophylactic opportunities of the venereal disease clinics. It is imperative that these clinics have larger physical facilities, as well as more clerical, nursing, and social service assistance, in order that they may take a proper part in the campaign for the eradication of venereal disease.

XIV. The Nursing Organization.—The nursing personnel of dispensaries is generally inadequate. The nurses are chiefly found in the children's, gynecological, surgical, and tuberculosis departments. Other departments are handicapped by lack of nursing assistance. Moreover, the nurses are frequently called upon to do other than purely nursing duties, and their assignment to the dispensary is often contingent upon the needs of the hospital. The practice established in certain institutions where a part of the course in the training school for nurses is devoted to dispensary work should be generally adopted and arrangements made in such a way that each of the pupil nurses would have several months' experience in the dispensary, which would be of great value to her. The pupil nurses should remain under the direction of a head nurse designated by the training school for the direction and instruction of the pupils. If such an arrangement could be effected in all the outpatient departments connected with hospitals maintaining a training school, the nursing service in dispensaries could be made much more adequate and economical than it is now, as the number of graduate nurses should be reduced to a minimum of one in some of the departments.

XV. The Social Service Department.—One of the most important adjuncts in a proper dispensary organization is the Social Service Department which should exist in connection with every dispensary.

The social service department could best do its work if it were in close cooperation with the admitting and diagnostic departments of the institutions. The patient's first contact should be, either with the social service department. where, upon rapid questioning, certain facts required by law would be ascertained about his social history, before he proceeds to the diagnostic or other departments of the institution, or this function could be performed by a proper registrar who, when directing the patient to the diagnostic clinic, attaches to his history sheet a slip to be returned by the physician with a check mark indicating whether or not the services of the social service department are required in the case. Such a routine procedure would automatically call the physician's attention to the availability of social service. Likewise a method should be worked out whereby reports on cases referred by physicians would automatically be sent to them as soon as available.

The social service department has become recognized as an important part of the dispensary and hospital organization and should be administratively incorporated as an integral part of the institution. It should be responsible before the Board of Trustees just as the other departments are, and all funds that are collected for its maintenance, if there be any special need for soliciting funds for any special department of an institution, should be placed in the treasury of the institution and paid out to the workers in the same way as salaries in other departments. There is an advantage, however, in having advisory committees of interested persons to discuss cases and to bring all the outside points of view and facilities available to assist in the work. On such committees, however, there should be representatives of the Boards

of Trustees, the administrative heads, such as the superintendent, the head of the training school for nurses, and also a representation from the several departments of the medical organization.

The work of social service has as yet not reached a plane where it can be said to be standardized in its aims and methods. It is still in a formative state. There is need for a concentration of effort on the part of all those interested to secure a crystallization of function and procedure.

XVI. Districting the City for Clinic Purposes.—In order that the dispensaries may become what it is possible for them to be, namely, important medical, public health, and social centers in the community, in addition to a reform of the present point of view and of the present organization, there is need of a better public appreciation of the scope and function of the dispensary and of a regional division of the city with regard to dispensary service.

The first could be accomplished through proper publicity on the part of the dispensaries, and by reports more informing than those published by most of the institutions. In the reports the work could be presented and analyzed in an interesting and instructive way, and the costs per patient or per attendance figured in accordance with an accurate and uniformly applied system.

The districting of the city for dispensary purposes may be difficult, because of the uneven distribution of the institutions and because of the needs of teaching clinics which do not desire to be restricted. In addition, there are a number of special institutions which cannot easily be included in any plan for the division of territory; likewise, denominational institutions might find it difficult to join in a district arrangement.

The advantages which would, however, accrue from a regional distribution of responsibility make it desirable to try such an arrangement. At first perhaps certain departments could organize their work on a district basis, following the successful example of cooperation on the part of the tuberculosis clinics. The pediatric, venereal disease, obstetrical, social service, and preventive medicine departments might find it most advantageous to adopt the district division of the field. Other departments might follow later, if these experiments should prove satisfactory.

The successful experience of the Association of Tuberculosis Clinics in raising the standard of equipment and procedure is worth while considering, particularly in connection with the venereal disease clinics, in which the variations in standards and records are so great at present as to render comparisons of their work of limited value. With a pooling of interests, and a uniform system of reporting and of scoring, great improvement could be expected.

XVII. Educational Opportunities.—The dispensary is destined to play an important part in the movement for disease prevention and public health education. Its opportunities are very large. People applying for relief to the dispensary are more in a mood to accept and follow hygienic advice than is the average person when in good health. There is a large number of dispensary patients whose condition could be remedied by a proper hygienic regimen and sanitary supervision. There is a need for a department of preventive medicine in many of the dispensaries, a department which would be responsible for the educational literature given out to patients, for classes in corrective exercises, in dietetics and such other group activities as require sanitary direction and supervision, and which would also be responsible for health exhibits at the clinic, moving pictures, and lectures; in other words a department which will make the dispensary a Health Center of its neighborhood.

THE BARBAROUS CUSTOM OF SMOKING.

By W. A. BLOEDORN, A.M., M.D.,
LIEUT.-COMMANDER, MEDICAL CORPS, U. S. NAVY.

THE world war is responsible for many changes in our social and economic life and there is no doubt that, due to its stimulus, national prohibition became a fact. The tendency in this direction has long been manifest but it required the excitement incident to the great conflict to secure the necessary legislation and to reconcile the people themselves to accepting national prohibition as a necessity.

One hears on all sides now the query, Will tobacco be next to go? and it is but natural that tobacco should loom up on the horizon, assume a position of greater importance and command more attention than ever before. The war has served to bring tobacco into the limelight and it may be interesting for us to inquire regarding its place in a civilized community, and the reasons for its almost universal use, before arriving at any hasty conclusions.

During the war, the demand for "smokes" for men in the service was enormous. Tobacco funds, subscriptions and donations, were sought from one end of the country to the other. Newspaper and periodical waged active campaigns for funds and with much success. This demand was not felt in the United States alone, but in all the belligerent nations similar campaigns were carried on, and even in the few neutrals the need for the sedative and soothing effects of Lady Nicotine were quite manifest.

This unprecedented demand was recognized by the government and the entire output of factories in some cases was taken over and sent directly to men in the service.

However, all this activity was by no means unopposed. There was much active criticism and opposition to the campaign on the part of many individuals, societies, and organizations. The harmful effects of the promiscuous use of tobacco were pointed out as well as the danger of encouraging and spreading a habit which was variously characterized as wasteful, extravagant, and unnecessary.

The opposition, however good a case they had, nevertheless appeared to be in the minority and the longer the war lasted the feebler became their protestations.

The fact remains that large amounts of tobacco were sent across to men in the service and equally large amounts consumed in camps on this side; in fact so great was the demand from these men that civilians in many cases found the weed difficult to obtain.

Now that the war is over and the troops are returning to civil life, what has been the effect of catering to this demand? Have the opposition proved their contentions? Has the promiscuous distribution of tobacco had a harmful effect? Were men rendered unfit for service by over indulgence in tobacco?

To answer these questions, the best evidence obtainable no doubt comes directly from the officers and men themselves.

That tobacco filled a much felt want by the men, there is abundant evidence to prove. That this craving was greater than would have obtained had these men remained at their usual occupations, must be admitted.

Let us analyze this demand. Upon entering the service the average man is surrounded by greater restrictions than he was accustomed to in civil life. His entire existence is subject to regulations. He arises in the morning, and goes to bed at night at a set time. His meals, his hours of drill, of recreation, and of liberty are fixed and vary but little from day to day.

The service means a complete change in many cases of habits and environment, the breaking up of family ties, and finally the inculcation of that sometimes elusive but necessary quality, discipline. It requires a readjustment of the individual to an entirely new situation in life. The ease with which this adaptation to a new environment is made has an important bearing on the future course of the individual.

It is here that the solace obtained from tobacco has a beneficial effect. It provides an outlet for pent-up emotion; it soothes, reconciles, and satisfies. A little philosophy inspired by a friendly smoke serves to ease an intolerable situation and the harshness of life appears less harsh when viewed through the haze of a fragrant cloud of tobacco smoke. When an individual can bring himself to say, "after all it might be worse," it is not necessary to surround him with guards to prevent suicide or desertion. And there is abundant evidence to prove that tobacco helps greatly to inspire such an attitude and does it with the minimum of after-effect.

Again, take the situation of the man at the front and about to get his first taste of shell-fire; awaiting for the order to advance, held in reserve, but likely to be called up any minute, with shells dropping about and an occasional comrade picked off, but still waiting. Inaction, having the appearance of calmness and yet great turmoil within, repressing emotions which struggle for expression; under these circumstances the cigarette becomes priceless. He selects one with great care, concentrates his entire attention upon preparing it. He lights it carefully, inhales deeply, watching the glowing tip intently. He blows out a large cloud of smoke and feels easier. He is doing something, he has found an outlet and this activity lessens the tension.

Again, after a hard day's work, tired, with food prepared with difficulty, depressed and somewhat homesick, ask the doughboy or sailor what he wants and invariably the answer is, "a smoke.'

Tobacco is a means of diversion which far from interfering with a man's performance of duty, attaches him to it and renders it less burdensome. In a campaign where a man's resources are so limited, there is nothing so trifling as to be devoid of value. And the testimony of men who have seen service is overwhelmingly in favor of its use.

But granting that it produces a good mental effect under these conditions, what about its effects on the physical man?

Also, now that the war is over and the men are returning to their more or less peaceful pursuits, why continue its use, in fact why not actually prohibit its use?

The effects of the habitual use of tobacco have been discussed from every conceivable angle and with much minuteness from the time of its first introduction, some investigators contending that it is entirely harmless when moderately used, while others ascribe numerous evils to its use. One French writer has gone so far as to attribute the defeat of his nation in the war of 1870 to the prevalence of cigarette smoking.

The effects of tobacco smoke are described by most investigators as being due practically entirely to the nicotine contained in it. There are other toxic constituents, but their quantity is so small as to be practicable negligible. The effects of nicotine vary considerably in different individuals. Considerable tolerance is acquired by continued use so that moderate doses soon lose all their unpleasant acute effects. However, absolute tolerance is never reached.

Increased pulse rate, heightened blood-pressure, irritable heart, and toxic amblyopia are a few of the untoward symptoms ascribed to the use of tobacco. And yet considering the large number of smokers we must admit that it is very rare that an individual seeks relief for one of the above conditions.

Let us consider the reasons for the use of tobacco in civil life. Why do people smoke? What is the basis of this almost universal craving which tobacco seems to satisfy? Will the withdrawal of tobacco entirely lead to any untoward effects?

If we smoke entirely for the physiological effects of the active principles of tobacco, which are absorbed during the act of smoking, we could obtain these active principles in pill or tablet form and administer them much more cheaply, accurately, and efficiently than by the act of smoking.

Yet who would be satisfied with a tablet containing his usual dose of nicotine instead of his satisfying after-dinner cigar? What soldier awaiting the order to advance would be soothed and calmed by a nicotine pill instead of his friendly cigarette?

We must go back further than the physiological effect of the drug itself to explain its action. The pleasure derived from a smoke is dependent probably more on the act itself than on the physiological action of nicotine and its allied alkaloids.

The pleasurable effect begins even before the

cigar or cigarette is lighted. The smoker carefully selects and inspects his cigar and the preparation of the tobacco for smoking receives much attention. All these things reflect the state of mind of the individual. Then the sound of the lighting match, the sight of the curling smoke and the glowing tip, the aroma of the burning leaf, the familiar taste, the touch and feel of the cigar or cigarette; all of these factors combine to produce the pleasurable effect. The appeal is not to one sense but to all the senses, and the psychic effect resulting from this stimulation of the senses is far more important to the smoker than the physiological effect of the nicotine absorbed. Destroy or impair any of the special senses and the effect of tobacco becomes immediately interfered with. It is a matter of common knowledge and observation among smokers when suffering from a cold which impairs the senses of taste and smell, that they derive little enjoyment from smoking.

Smoking in the dark or when unable to see the smoke or the glowing tip is most unsatisfactory. In other words, while the action of nicotine and the associated active principles of tobacco is probably in some degree responsible for the effect of tobacco, it would appear to be nearer the truth to say that men smoke in spite of this action and not because of it.

The increased pulse rate and heightened blood pressure noted in some cases following the use of tobacco and ascribed by investigators along this line to nicotine absorbed, are not conducive to pleasurable sensations on the part of the individual concerned and we are safe in assuming that it is not for this effect that he indulges in tobacco.

The effects which appeal more to the smoker are soothing, sedative, tending toward relaxation, contentment, and mental rest. He appears less acutely aware of his own shortcomings and more tolerant of the shortcomings of his associates.

The history of tobacco, its discovery, and use in the New World, its introduction into the Old World, and the manner in which the habit is spread form an interesting chapter and one which is well worthy of investigation. Its use was unknown to Europeans before the discovery of the New World, but following its introduction the habit spread with great rapidity despite the most vigorous means taken to stamp it out. Among the aborigines of America the use of tobacco was widely prevalent.

The practice of smoking was observed by the companions of Columbus on their first voyage. It was first introduced into Spain by some of the followers of Columbus on his second voyage, who returned about 1512. Introduced into the British Isles about 1560 it was not until 1586 that the plant and its use were widely known and that Raleigh distinguished himself by growing tobacco on his estate and himself smoking publicly.

From Spain and England the use of tobacco spread by degrees over all the known world. In America the culture of tobacco began in Virginia with the earliest settlement of the colony. It is recorded that in 1615 the gardens, fields, and even the streets of Jamestown were planted with tobacco, which immediately became, not only the staple crop, but the principal currency of the colony. In 1619 "ninety agreeable persons, young and incorrupt," and in 1621 "sixty more maids, of virtuous education, young and handsome" were sent out from London to provide wives for the colonists. The first lot of these ladies was purchased by the colonists for 120 pounds of tobacco each; the second lot brought 150 pounds each.

Nevertheless, there is evidence to show that the early explorers of the New World regarded the custom of smoking as the extremity of barbarism. Nor have advocates of this view been lacking from that day to this. But, in spite of all objections, tobacco has extended its reign over the entire earth. It is an important source of revenue to the most enlightened of governments; its devotees include men of all ranks and all races from the Eskimo to the Central African savage.

However, this did not come about without vigorous objection by Church and State, and severe penalties and punishments were tried in many countries to stamp out the habit, but without success.

James I was particularly bitter in his denunciation of the use of tobacco. He raised the duty from twopence per pound to the enormous sum of two shillings and tenpence. In 1619 he commanded that no planter in Virginia should cultivate more than 100 pounds, and in 1624 he prohibited the planting of tobacco in England and Ireland. A portion of his famous "Counterblast against Tobacco" reads as follows: "A custom loathsome to the eye, harmful to the braine, dangerous to the lungs, and the fume thereof nearest resembling the horrible Stygian pit that is bottomless."

It is an historical fact that both James I, Charles I, and Charles II as well as Cromwell had the strongest dislike of the Indian weed and lost no opportunity to suppress its cultivation and use.

Pope Urban VIII excommunicated all who took snuff in church.

Christian IV of Denmark had all smokers and snuffers publicly whipped.

The Chinese and Japanese punished smokers by whippings and maimings.

The Russian rulers cut off noses and the Turks stuck pipes through the noses of smokers and exhibited the victims in public. Amurath IV of Turkey beheaded everyone found guilty of smoking.

In spite of such powerful foes, the custom increased to such an extent that when William ascended the throne, it was said to be almost universal.

Penalties are still imposed on the users of tobacco in the form of taxes which constitute an important source of revenue to the government.

Thus, this habit, learned from the savage, came gradually to be accepted as the natural order of affairs, and so the barbarous custom of smoking has become almost a universal habit of civilized nations and has created an ever increasing demand for the weed.

The average individual begins the use of tobacco in early adult life. The reasons for beginning its use vary with the individual, but when sifted down invariably fall into the same class. The individual smokes because he observes other people smoking and these people appear to derive enjoyment from it. His companions and associates use tobacco and it is apparent to him that they derive considerable satisfaction from its use. He goes to dinner and

following dinner he observes his host and fellow guests select and light their after-dinner cigars. They sit back in their chairs and blow fragrant clouds of smoke toward the ceiling. They relax and appear to be at ease and the observer, noting these phenomena, is tempted to avail himself of the weed. From constantly associating with smokers and with tobacco readily obtainable, it is but natural that he should acquire the habit.

The fact that the first few attempts may produce far from pleasurable sensations does not deter him. The habit once acquired in the great majority of cases continues through life.

In times of stress he resorts to it as well as in idle moments. For the tired business man the after-dinner cigar is often the prelude to an hour of relaxation, recuperation, and mental rest. For the laborer after a hard day's work the solace of the evening pipe tends to soothe the ache of tired muscles.

The tension under which we appear to live, the continual striving for gain, for advancement, in many cases for even the necessaries of life, the petty annoyances, grievances, and worries which enter our daily life; the restlessness, the lack of contentment which is everywhere manifest, all these factors create a demand which must be satisfied.

For some alcohol supplied the demand, for some drugs, for others the theatre, athletic sports, moving pictures, motoring, and hunting.

But the demand exists and there is abundant evidence to prove that tobacco answers this demand more universally than any of the other sedatives mentioned, that it reaches a larger mass of people, and that it accomplishes its purpose with the minimum of after effects.

We have made national prohibition a fact, and wisely so; we have surrounded habit-forming drugs with the most stringent laws that legislators have been able to enact. In our zeal for reform let us not allow the pendulum to swing too far and attempt to prohibit the use of tobacco without a careful analysis of the place it has come to occupy.

There are some individuals who cannot use tobacco, there are some who should not use it, there are some who use it to excess and who suffer in consequence. There is on the other hand a large army of moderate tobacco users, who indulge for years without appreciably bad physical effect and with good mental effect. Each individual must be his own judge as to whether he can use tobacco safely and also as to the amount he can tolerate.

There can be little doubt that tobacco helps to ease difficult situations in civil life as well as at the front. It provides an outlet for many individuals, readily available, a sort of safety valve.

You are held up by traffic congestion on the way to your office; you puff your cigarette faster while waiting for the line to move; your decision is necessary on some important undertaking; you think it over with the aid of a soothing smoke. Following dinner your host passes cigars, and under the influence of tobacco you feel less restraint, more at ease; you converse better and an atmosphere of well-being and good fellowship is inspired.

Consequently the almost universal character of the habit is not difficult to explain. That its use to excess leads to harmful effects there is no doubt. There is no general rule which can be laid down for all to follow. Each individual knows as a rule when he is exceeding the amount he may safely take. It would appear that it is the abuse of tobacco instead of its use which is responsible for the harm it may do.

Before attempting to legislate it out of existence let us analyze the origin of its enormous demand. Reduce the tension under which we live, relieve the fierce struggle for existence, the crowding, the jostling, the striving for advancement, for gain; provide a means of relaxation, of recreation, and we shall have gone far to supply a substitute.

The tobacco habit may be likened in many respects to the tea and coffee habit. Each may do harm in some cases; each may also be a source of comfort and solace in others. Under ideal surroundings and environment the demand for each would probably disappear. In themselves they cannot be classed as foods, or even as necessities. Many people would no doubt be better off without them. But for a large mass of people they have come to occupy an important place.

Tobacco is used by all races from the most savage to the most civilized, in the frozen arctic regions as well as in the tropics, and by the rulers of nations as well as the lowest subject.

If you class tobacco as a form of dissipation, at least you must grant that it is a mild form of dissipation. If you would deprive the individual of his tobacco he would be justified in making the same demand regarding your tea or coffee.

Before attempting to prohibit its use, take into consideration the social and economic conditions which are in great measure responsible for its demand. Correct these conditions, relieve this demand or provide substitutes and then advocate if you will the prohibition of tobacco.

SOME UNUSUAL SYMPTOMS AND SIGNS OBSERVED IN THE LAST INFLUENZA EPIDEMIC.

By DAVID GREENBERG, M.D.,

NEW YORK.

ADMITTING PHYSICIAN AND ASSISTANT IN PATHOLOGY LEBANON HOSPITAL.

In the recent epidemic of influenza, much was learned as to great variations in the clinical picture which this disease may assume. While the vast majority of cases were similar in their onset and clinical course, others were atypical in their onset and presented during their course many unlooked-for symptoms and complications, often throwing doubt on the original diagnosis until cleared up by further development or laboratory findings. It may be worth while, therefore, especially in view of the expected increase in the number of cases of influenza in the coming months and perhaps years, to record some of the less common manifestations observed in a comparatively small group of cases. This can best be done by reporting the cases in which these rarer symptoms occurred.

Case I.—*Influenza with Intestinal Hemorrhages.*—B. L., female child, aged 6 years. Brother had typhoid fever three years ago; influenza seven days ago. The

patient had measles at the age of two, several attacks of tonsillitis, the last one about one year prior to the present illness. She became ill on the afternoon of February 13, 1919, with headache, sore throat and fever; vomited twice. The child was seen on the evening of the same day and then had a temperature of 103.4°, throat and conjunctiva red, otherwise negative. On the next day the temperature was 101, slight cough and sneezing. Throat culture taken on previous day negative. Urine, faint trace of albumin. For the following two days the temperature was fluctuating between 100-103°, usually higher in the afternoon. The patient felt fairly comfortable except for a moderate cough and some sneezing.

On the morning of the fourth day of illness the temperature was 100.5°, but there were present a few coarse râles over both bases. In the afternoon the patient complained of some abdominal pain, and about two hours later passed a large bloody stool. The blood was bright red and mixed with feces. When the child was seen about one hour later the temperature was 97.6°, and she looked well. She had no air-hunger, no pallor, and the pulse was about 100 and of good quality. Within the following sixteen hours three more bloody stools were passed. The râles in the lungs were not heard at this time, but she had congestion of both ear drums. On the following day (fifth day of illness) temperature was 101°, there was present a small patch of consolidation over the left base, and evidence of congestion over the right base. The blood count at this time was: Red blood cells, 4,200,000; hemoglobin, 67 per cent.; white blood cells, 11,800; polymorphonuclears, 49 per cent.; lymphocytes, 41 per cent.; mononuclears and transitionals, 10 per cent. Spleen not palable nor enlarged on percussion; Widal negative. Two more bloody stools were passed on the next day (seventh day of illness). These were tarry and showed large quantities of blood, both microscopically and chemically.

The lung signs did not change for the next two days, dulness, bronchial breathing, and fine râles persisting. The temperature came down gradually (lysis) and there was no more blood in the stools. On the ninth day of illness there were signs of resolution. The blood count then was hemoglobin 75 per cent., red blood cells 4,400,000 and white blood cells 4,200, differential polymorphonuclears 42 per cent., lymphocytes 53 per cent., mononuclears 5 per cent. Sputum examination showed no blood, no tubercle bacilli, many staphylococci and streptococci, no influenza bacilli. Stool culture, urine culture and Widals negative.

Case II.—*Influenza with Onset of Hematemesis.*—B. S., male, aged 26 years. Became ill on morning of November 14, 1918, with slight headache. Was on his way home when he vomited a large quantity of coffee-ground material. After he had reached home and was put to bed I saw him and, while being examined, he again vomited coffee-ground material well mixed with milk curds. The temperature at that time was 102.4°, pulse 100, respiration 18. There was nothing in his previous history pointing to gastric or duodenal ulcer, no evidence of bleeding from nose or throat, no cough and no tenderness over abdomen. The rest of physical examination also negative. On November 15 passed a tarry stool which was positive for guiaic, and had a temperature of 103.6°, congested eyes and throat and complained of headache. Blood count at this time: Red blood cells 4,800,000, white blood cells 5,800, polymorphonuclears 51 per cent., lymphocytes 46 per cent., mononuclears 3 per cent. November 17, temperature 104.8°, pulse 104, respiration 30, looked fairly ill, moderate dulness and fine moist râles both bases, especially left. November 20 (sixth day of illness), signs and symptoms same. November 24 (tenth day of illness), left side clearing up, moderate dulness only. November 27, temperature normal, no signs. The sputum was examined daily, nothing found. The patient made an uneventful recovery.

Case III.—*Influenza Followed by Acidosis and Toxic Vomiting.*—Mrs. W., aged 26 years. Married three years. gave birth to twins two years ago. One child died twenty-four hours after birth; probable cause, premature birth (it weighed 4 lbs.), the other twin living and became ill two days after the onset of the mother's illness, developing influenzal bronchopneumonia and double otitis media. Menstruation regular every twenty-eight days; none for past three months on account of pregnancy.

The patient became ill on January 28, with sudden onset, sore throat, chilliness, and dry, irritating cough. The physical examination was negative except for temperature and markedly congested throat. The temperature was irregular for the next four days, ranging between 100° and 103.6°. On the fifth day of illness the temperature was 102.8°, pulse 78, respiration 26, cough less severe, but expectorated bloody mucus. Examination at this time disclosed a small patch of dulness, bronchovesicular breathing, and fine moist râles at about the level of the right angle of the scapula, extending totward the spine. Blood count on that day showed white blood cells 9,000, polymorphonuclears 60 per cent., lymphocytes 32 per cent., and mononuclears and transitionals 8 per cent. The urine showed the presence of albumin and a few hyaline and granular casts.

On the sixth day of illness the temperature was lower, 101.5.° The signs did not extend, but remained stationary for the next seven days, even after the temperature had come down to about normal, which occurred on the tenth day of illness.

On the eleventh day of illness the patient began to vomit and vomited continuously regardless of the nature of the food ingested. The vomiting became progressively worse within the next forty-eight hours, so that at the end of the second day, after vomiting began, she could not retain as much as a teaspoonful dose of water or bicarbonate solution. Introduction of water by rectum did not affect the rapid dehydration. Urine examination showed a heavy reaction for both acetone and diacetic acid, but no albumin or casts. It was decided, therefore, to take her to Lebanon Hospital, with a view of giving her alkalies and carbohydrates subcutaneously or intravenously. The introduction of 800 c.c. 5 per cent. bicarbonate solution had no effect on the vomiting and the patient began to sink rapidly. I then consulted the attending obstetrician. who, after seeing the patient with me, advised a rapid emptying of the uterus, which was done under a light anesthesia. Three hours after the interruption of the pregnancy the patient began to retain fluid and made an uneventful recovery.

Case IV.—*Influenza with Acute Nephritis and Suppression of Urine in a Patient Suffering from Pulmonary Stenosis and Paroxysmal Tachycardia (Auricular Fibrillation).*—N. H., male, aged 21 years. Mother and one brother died of tuberculosis, mother at the age of 43 years and brother at the age of 20 years. One brother ill with mitral disease, one sister with chronic pulmonary tuberculosis.

The patient has been under medical supervision since he was about 12 years of age. He was told that he has heart trouble. He came under my observation about four and one-half years ago, when he was suffering from slight dyspnea on exertion and general weakness. My examination at that time revealed the presence of a feminine type of development as regards general contour of body and distribution of hairs, and infantile genitalia. He also showed the presence of a moderately enlarged heart, especially to the right, a fairly diffused apex beat and slight pulsations in second and third interspace with each heart beat. On auscultation there was heard a loud rough systolic murmur over the base of the heart, with maximum intensity over pulmonary area and thrill in the same place. The murmur was transmitted to the large vessels of the neck. He did fairly well for a while, but developed, within the last two years, attacks of great weakness which are apt to come on almost any time. These attacks are associated with a very rapid, thready, and irregular pulse. The rate varies from 150 to 200 and lasts from two to four hours. The last attack occurred about three months prior to present illness and lasted five hours. During these attacks patient is pale and looks greatly distressed. He is perfectly conscious but very weak, and talks in a whisper. He is usually covered with cold perspiration and toward the end of an attack the pulse becomes more irregular, but of better quality, and usually returns to normal wtih a few deep inspirations.

Present Illness.—Acute onset with headache, very sore throat and high fever, 104.2°, epistaxis on the second day of illness. On the third day of illness he developed

complete anuria, which lasted about thirty-six hours. On the introduction of a catheter, after thirty hours of anuria, about 4 c.c. of bloody urine was obtained. During the period of suppression of urine he vomited three times and had slight edema of eyes and extremities, but had no twitching or convulsions, no diarrhea, and mind was perfectly clear. On the fifth day of illness he began to pass urine and passed 20 ounces of bloody urine, but continued to pass blood in his urine for about thirty days.

On the fourth day of illness, while in a warm pack, he developed an attack of tachycardia as heretofore mentioned, lasting about sixteen hours. He had a very rapid, thready, irregular pulse. The radial pulse was about 130, while the apex beat rate was almost 200.

On the fifth day of illness patient developed an extensive urticaria, which lasted for about ten days. The rash was especially marked on the extremities and was extremely itchy. I was inclined to attribute this to the quinine which he was getting early in the disease. This patient ultimately recovered, but he still has an occasional trace of albumin, while during the height of the disease he had casts, hyaline and granular, as well as pus cells in addition to the blood.

Comment.—In this small group of cases hemorrhage from the stomach, from the bowels, acute nephritis with suppression of urine, urticaria (which may or may not be a drug rash), acidosis with toxic vomiting, indicating the protean nature of this disease, were observed.

It is quite obvious how difficult it may at times be either to make a diagnosis of or to rule out influenza, in obscure cases. Until the etiology of this disease is established more firmly—as it is in the case of typhoid fever or tuberculosis, where, when in doubt, we may call on the laboratory worker to isolate the causative organism—we are in a very similar position regarding influenza as were our predecessors of some thirty years ago, when malaria was the most frequent diagnosis made, especially in acute febrile diseases.

1220 Grand Concourse.

A NEW METHOD OF TREATING REMOTE MANIFESTATIONS OF GONORRHEAL INFECTIONS.

By MAXIMILIAN STERN, M.D.,

Attending Urologic Surgeon, Broad Street Hospital.

AND

I. SIDNEY RITTER, M.D.,

New York.

Assistant Attending Urological Surgeon, Broad Street Hospital.

In July, 1919, our attention was called to the treatment of gonorrheal arthritis by means of a non-specific protein. Up to this date we had treated all such cases by means of vaccines, internal medications, and local measures.

Upon investigating the subject of non-specific protein therapy, it was found that the *Bacillus typhosus* was used by the majority of investigators in this field. All reported a reaction following the intravenous injection of the emulsion. The patients were very sick for from 24 to 48 hours, having severe chills, high temperatures, and increased leucocytic counts. This reaction was essential in effecting a relief or cure of the existing arthritis.

At the Broad Street Hospital, New York City, a ward has been set aside for the care of venereal patients. Here a number of cases of gonorrheal arthritis, epididymitis, orchitis, prostatitis, and chronic gonorrhea are treated regularly. Beginning in July, all cases of arthritis were given intravenous injections of 20 c.c. of a solution of sodium iodide, 2 gm. to the 20 c.c. This treatment was repeated every four days.

The first case treated responded so incredibly to the injections, that it was thought possible that the drug might not be wholly responsible for the prompt amelioration of the symptoms. It was therefore decided to proceed with a series of patients so afflicted.

After having treated ten arthritis cases, with extraordinary results, the use of the intravenous injection of sodium iodide in other conditions was determined upon. This seemed logical in acute orchitis, inasmuch as many of the joint cases which responded so quickly, were also in the acute stage. Again we were astonished to note the rapid subsidence of the acute symptoms.

Being thus encouraged by the way that the arthritis and orchitis cases yielded, we next proceeded with the treatment in a series of prostatic infections, which also behaved in a manner quite different from that which we had been accustomed to seeing.

By thus extending the field of application of this treatment, we have now records of 100 cases discharged germ free and apparently cured, though no follow-up system was possible in the class of cases treated, who were all seamen.

Before citing cases to illustrate the response to this form of treatment, it should be mentioned that all the usual therapeutic measures were employed in conjunction with intravenous medications.

Case I.—Mr. J., age 24, laborer, came to the Broad Street Hospital on July 10, complaining of pains in both ankles, right shoulder, and neck. He had had an acute gonorrhea two years previously, complicated with an orchitis. He was treated locally for six months, and was discharged as cured. One year ago he began to have trouble in walking, due to pain in his heels. He went to his physician who said he had gonorrheal rheumatism, and was treated with massage of the prostate and intramuscular injections of vaccine. He was slightly improved after six months' treatment and went back to work. Two weeks ago the pain in the heels returned, together with pain in the shoulder and neck. He has been in bed up to to-day, and was brought to the hospital in an ambulance.

July 12, he was given an intravenous injection of sodium iodide; forced fluids; massage of the seminal vesicles; and hot colonic irrigations twice a day. Twenty-four hours after the injection, the patient said he felt a little better; he could move his right shoulder without pain.

July 15, the patient was given his second injection; the local measures being continued. After the sixth injection the patient was able to get up and about, and showed marked signs of improvement.

Aug. 10, the patient was discharged from the hospital, able to walk without any pain.

Case II.—Mr. S., age 22, seaman, reported for treatment to the Genito-Urinary Clinic at the Broad Street Hospital. He had had a gonorrheal urethritis for two months, and had been treated locally by a physician.

On examination a very small external meatus was found completely filled with pus. A smear showed many gonococci both intra- and extra-cellular. The patient said he had been unable to irrigate himself, due to the small meatus. Further examination revealed a markedly swollen right testicle, very tender, which made walking very difficult.

A meatotomy was performed, the urethra was irrigated and sodium iodide was injected intravenously. He reported back the next day to the clinic and said he had no trouble walking; his testicle was not as

tender as it had been. A second injection was given in three days; eight days following which the orchitis had completely subsided.

CASE III.—Mr. T. H., age 20, English seaman, was admitted to the Broad Street Hospital with an acute prostatitis and orchitis, difficulty in voiding urine and defecating. Examination revealed a large fluctuating right lobe of the prostate which was very tender.

Aug. 30, he was given hot colonic irrigations, put on urotropin, with ice applied locally to the scrotum. An intravenous injection of the iodide was also given. At night the pain was so severe that morphine was necessary. The following day, patient still complained of some pain, but said he felt a little better.

Four days later, a second intravenous injection of sodium iodide was given. That night the patient slept without any narcotics. Two days later, rectal examination showed a much smaller prostate, no fluctuation and no tenderness. The orchitis had also cleared up. The patient was treated for the existing urethritis.

Comparative Rationale of the Action of the Intravenous Injections of Sodium Iodide to the Intravenous Injections of Non-Specific Protein.—In comparing the actions of the intravenous injections of the non-specific protein to that of the intravenous injection of sodium iodide, we arrived at the conclusion that there was much in favor of the latter, both in positive results and in absence of disagreeable features and dangers.

The temperature in patients treated with the intravenous administration of non-specific protein is reported as reaching 105° to 106° in all cases that respond to the treatment. This necessitates the patient remaining in bed or at the hospital for a few days after each injection. Following the intravenous administration of sodium iodide, no patients have had any noticeable rise in temperature. The patients were permitted to be up and about immediately following the injection. This makes office treatment possible without any dangers. The pulse rate is increased in proportion to the temperature in the non-specific protein treatment, whereas there is no change following the injection of sodium iodide.

Blood Pressure: We have at no time noticed any change in the blood pressure following the administration of sodium iodide. The non-specific protein therepy has shown a marked fall in blood pressure, following some injections.

Kidneys: No suppression of urine or any signs or symptoms of acute nephritis were present in any of the cases injected with sodium iodide, whereas cases of acute nephritis have been reported following non-specific protein treatment.

Leucocytosis: Blood counts were made 4 and 12 hours following the injection of sodium iodide without any noticeable change in the leucocytic count. The non-specific protein is said to give a very marked leucocytosis, in fact the cure seems to be dependent upon a rise in the leucocytic count.

Chills and General Malaise: These were never present following injection of sodium iodide.

Conclusions.—1. The intravenous injection of sodium iodide has produced no untoward effects upon the patients so treated and is therefore a good office as well as hospital procedure.

2. The results obtained in acute gonorrheal arthritis, orchitis, and prostatitis demonstrate its value in remote manifestations of gonorrheal infections.

3. An entire dose of the drug was injected into the tissues in one patient. He complained of a great deal of pain for about one hour. There was neither edema nor redness a short time following the injection. The drug therefore, even if not introduced entirely into the vein, will not cause any sloughing.

At this writing, a conclusion as to the manner in which the iodide produces its results has not as yet been determined upon; but in three classes of gonorrheal infection, herein alluded to, the behavior of the patients while thus treated, was in general quite different from that to be expected without it, and reduced their hospital days about one-third.

219 WEST EIGHTY-FIRST STREET.

Medicolegal Notes.

Basis of Physician's Opinion—Medical Works In Evidence.—In an action for injury to the plaintiff's eyes from an explosion of electric light lamps in a street car, due to contact with defective trolley wires, the plaintiff claimed that he was permanently blind in both eyes. A physician was called as an expert witness by the plaintiff, whom he had examined since the action was begun, but had never treated, and he was allowed by the trial court to give an opinion that the plaintiff was totally blind in his left eye, basing such opinion in part upon his examination and in part upon subjective symptoms, or upon what the plaintiff had told him. The Wisconsin Supreme Court holds that this was error, and that a physician who treats a patient may give an expert opinion, based upon the result of his examination and statements made to him by the patient, but not one who does not treat the patient. The reason for the application of different rules to the two cases is stated thus: When a patient submits himself to treatment, he does so for the purpose of curing himself of the malady afflicting him, and he is desirous to do so, and the presumption is that he will tell the truth to the doctor. If he does not, he knows that not only may a cure not be affected, but he may seriously jeopardize his health by giving false information or withholding important information. But when he goes to a doctor for examination for the purpose of having him testify, but not treat him, he runs no risk in giving false information, and the inducement may be to hide rather than to reveal the truth.

Another medical witness was called as an expert by the defendant, and the plaintiff admitted his qualifications to testify as such. On cross-examination he was asked by the plaintiff's counsel if he considered Oppenheim an authority on optic atrophy. On receiving a qualified negative answer, and the statement that the witness had read a part of Oppenheim's works, he was asked if he remembered having read a passage from one of Oppenheim's works, which was read to him. He stated that he could not recall having read it, and that he could not deny that it was a correct statement of what is generally taken to be the effect of dazzling on the human eyes by men skilled in the medical profession. It was held that under the decisions of the Wisconsin Supreme Court the admission of this evidence was erroneous. The reason given is that if under the guise of finding out a witness' familiarity with the contents of medical works you can read extracts therefrom to him and inquire if he is familiar with them, then you can get the contents of every medical book before the jury. This the Wisconsin court has declared cannot be done. In Zoldoske v. State, 82 Wis. 605, 52 N. W. 786, it said: "Text-books or scientific works cannot be read in evidence to the jury, and the rule cannot be defeated or evaded by getting their contents before the jury by having a witness testify to what they contain." The court added that it cannot be done by asking him if he is familiar with such and and such a passage, reading it; for that places the contents of a medical book just as effectively before the jury as though the book itself were introduced.—Bell v. Milwaukee Electric Ry. & Light Co. (Wis.) 172 N. W. 791.

Expert Evidence.—Experiments as to Gunshot Wounds.—In a homicide case, where the defense was suicide of the deceased, the Maryland Court of Appeals held that it was proper to allow a physician to use the pistol with which the wound was inflicted, to which he attached a stick to explain his testimony as to the course of the bullet. The postmortem examination had shown that the deceased, a woman, had died from a gunshot wound of the right chest, the ball entering two inches above and three inches to the left of the right nipple, and that the ball went from right to left and from below slightly upwards. There were powder marks on the palm surface of her right hand, and powder grains burned in the wrist of the right hand from explosion, and the white shirt waist which she wore was burned, but to what extent was not shown. It was held proper for the physician, who has qualified by evidence that he had examined other gunshot wounds and had made experiments, to testify regarding the effect of experiments made by him with the same revolver and ammunition which caused the deceased's death in order to show the distance between the deceased and the pistol with which she was killed. These experiments were held admissible as tending to refute the testimony of the accused that the wound was self-inflicted under the rule, based upon the authority of many cases in different states, that experiments tending to show that an occurrence could not have happened in the manner in which it is alleged to have happened are competent evidence in both civil and criminal cases. It must, however, be shown that such experiments were conducted under similar or substantially similar conditions as those existing at the time of the occurrence in question.—Newkirk v. State (Md.), 103 Atl. 604.

Signature of Death Certificates.—In answer to a request for their opinion from the Governor of the State of Rhode Island on the point, the justices of the supreme court of that state are of opinion that persons who have received from the state board of health certificates to practice osteopathy, under R. I. Pub. Laws 1914, chapter 1058, and who have registered under Gen. Laws 1909, chapter 193, in the town clerk's office their authority so to practice, are entitled to sign death certificates, where last in attendance on the deceased, as "physicians registered to practice," within Gen. Laws 1909, chapter 121, section 7, as amended by Pub Laws 1910, chapter 575, section 2.—*In re* Opinion of the Justices, 107 Atl. 102.

Dying Declarations as Evidence.—To render a dying declaration admissible in evidence, in a homicide case, it should be made to appear clearly that it was made under a sense of impending death, and that all hope of recovery was gone. This may be made to appear from what the injured person said, or where, from the nature and extent of his injuries, it is evident that he must have known that he could not survive. It is sufficient if it satisfactorily appears that the declaration was made under a sense of impending death, whether it be directly proven by the express language of the declarant or be inferred from his evident danger, or the opinions of the medical attendants, stated to him, or from other circumstances of the case, such as the length of time elapsing between the making of the declaration and his death. It is for the court to consider from the evidence whether a declaration was made under circumstances rendering it admissible as a dying declaration, and the credibility to be attached to a dying declaration is a matter for the jury.—Allen v. State (Okla.), 180 Pac. 564.

Impairment of Vision—Expert Examination.—In a personal injury case, where the plaintiff had voluntarily exhibited an injury to his head to the jury for inspection, and the defendant moved the court to compel the plaintiff to submit to a physical examination of his head by physicians named by the defendant, it was held error to deny the defendant's request. The courts have uniformly held that, where a plaintiff in a personal injury case voluntarily exhibits the injured part of his body to the jury for inspection, the portion of his body so exhibited becomes an exhibit in the case, like any other object or thing introduced in evidence, and the opposite party has the right to make such inspection of it as will enable him to explain, criticize, or impeach its value as evidence, and to that end have it examined by experts, and these may be of the defendant's own selection. The plaintiff claimed that the sight of one of his eyes had been affected by the wound in his head. The court said that it is a matter of common knowledge, of which courts will take judicial notice, that the question of the impairment of vision is capable of exact demonstration by expert examination, and in the present case, when the plaintiff put his head in evidence and permitted the jury to examine it, unless the eye which he complained of was put out, the jury could in no manner determine the extent of the injury to it, if any, but with the aid of experts the matter was capable of exact determination.—Holton v. James (New Mex.), 183 Pac. 395.

Cross-Examination of Expert Witnesses.—The Missouri courts hold that expert witnesses may be cross-examined, and their opinions obtained, based upon other states of fact, assumed by the party examining them to have been proven upon a hypothetical case, and they may be cross-examined on purely imaginary and abstract questions. Such questions are not only permissible in order to get the opinion of the expert witness upon all the possible theories of the case, but they are allowable, also, to test the value and accuracy of the opinion of the witness himself. Sparks v. Harvey (Mo.), 214 S. W. 249.

Liability Not Determined by Possible Results of Operation.—In an action against a surgeon for personal injuries it appeared that the plaintiff, as the result of a collision, sustained a broken collar bone and a severe injury to the brachial plexus, which caused paralysis of his arm. The defendant treated him for six weeks, after which he went to a hospital and was there unsuccessfully operated upon, the arm being useless at the time of the trial. The plaintiff's claim was "that the defendant carelessly and negligently failed to operate upon the injured parts of the plaintiff's body seasonably, and that he failed to exercise that judgment which he professed to possess in the treatment of the plaintiff's injuries." The Supreme Judicial Court of Massachusetts sustained exceptions to the trial court's refusal to direct a verdict for the defendant. It held to be prejudicial error a charge permitting the jury to consider whether or not "there was a possibility not of entirely remedying the condition of the nerves, but mitigating the consequences in some degree by an operation." The appellate court holds that the defendant's liability was not to be determined by the jury upon consideration of contingent, speculative, and possible results of an operation which might be performed upon the plaintiff to remedy or mitigate the consequence of the injury to the nerves, but upon proof by a fair preponderance of evidence that it was reasonably possible that such a result would follow an operation, performed by the defendant with the ordinary skill and ability of surgeons practicing in towns similar to the one where the defendant undertook to practice his profession.—Tucker v. Stetson (Mass.), 123 N. E. 239.

False Answers in Insurance Application.—In an application for life insurance, the applicant answered that he had had none of the diseases indicated or specified in a certain question, and that, save in a single instance —of temporary malaria—he had not consulted any physician for any ailment or illness not included in that question. It was shown, in an action on the policy issued on that application, that, within the two or three years preceding the application the applicant had, on several occasions, consulted physicians, had been told that he had a bad heart and had been treated for it, and though not informed, in so many words, that he had Bright's disease, had, within a few weeks prior to the making of his application, three times called upon and consulted his physician, by whom, on each occasion, a certain familiar test was made to determine the question of the existence or progress of that disease. It was held that the statement in the application was untrue to the knowledge of the applicant; that the defendant would not have issued the policy if informed of the tests, without knowing the results; that the statement therefore operated to deceive it and induce it to issue the policy; that the deception related to a material fact of which the defendant was entitled to be informed; and that, whether the statement was regarded as a representation or as a warranty, there could be no recovery on the policy.—Lee v. New York Life Ins. Co., Louisiana Supreme Court, 80 So. 652.

New York, January 31, 1920.

THE SYMPTOMATOLOGY OF THE SWEATING SICKNESS.

THE first appearance of the sweating sickness occurred in England in 1445 and epidemics recurred off and on until 1486. Then in 1507 and in 1518, the disease was described under the names of pestis britannica, ephemera britannica, sudor anglicanus, hydropyretosis, hydronosis, etc. It appeared in France for the first time at Montbéliard, in 1712, if we can rely upon Allioni's statement in his work, "Tractato de miliarum origine, progressu, natura et curatione," published in 1758. The disease has reappeared a number of times in France since its first epidemic, the last being in Les Charentes, from May to July, 1906. From 1821 to 1906, there were eleven epidemics of the sweating sickness in different parts of France, the mortality being respectively 5, 9, 7.4, 1.7, 10, 5.5, 12, 10, 10, 6 and in the last, that of 1906, 1.8 per cent. These figures show the great difference in the virulence of the disease in the various epidemics. It is to be remarked that the epidemics are confined to the country and that large or small cities remain free. Women are somewhat more prone to develop the disease than men, while children generally escape.

The onset of the affection is usually very sudden and ordinarily occurs in the middle of the night, with an extremely profuse sudation, pain in the epigastric region, headache, palpitation, excessive thirst, chills, and precordial distress, which awaken the patient who had retired feeling perfectly well. Some observers have maintained that the patient did not feel well for several days before the onset of the disease, but it is doubtful if this is correct, and the many competent physicians who followed the epidemic of 1906 do not hesitate to maintain that the onset is sudden, without prodromes. Sweating is severe, to such an extent that cases have been met with which necessitated a change of bed-linen twenty times in a single day. In two or three days the sudation ceases, when the eruption appears, this usually being on the fourth day of the disease. The subject of the temperature which accompanies the onset of the disease has given rise to considerable discussion. Haury found an average temperature of from 38° to 38.5° C. (100.5° to 101.3° F.) only during the period of the eruption, while Dartigolles found it to be in some cases as high as 41° to 42° C. (105.8° to 107.6° F.) and even 43° C. (109.4° F.) in a few. The charts showed a sudden rise.

The second symptom of the affection is the eruption, which usually develops on the fourth day, sometimes on the third, although it has been known to appear as late as the end of the first week. It is preceeded by a disagreeable constant pruritus preventing sleep, or the patient may complain of tingling or severe pricking sensations. The pruritus is located over the areas on which the eruption will develop. This represents the dangerous phase of the disease. The eruption begins on the sides of the neck, the flanks, the anterior aspect of the forearm and wrist—which are sometimes swollen—and over the front of the thorax. The skin is rough to the feel on account of the numerous very fine papules which cover the exanthematic areas; these are at first very indistinct, especially on the hands, but are not long in becoming characteristic on the other portions of the body. The face is usually congested, sometimes highly so, but it would seem that the eruption, when it does develop, is never very pronounced. It is occasionally found behind the ears and on the chin and forehead, but only in a discrete way. The eyes are brilliant, the lids red. The eruption next extends to the back, shoulders, chest, and lastly, but in a lesser degree, to the lower limbs, when it becomes generalized, as is sometimes the case. The papules soon project, become conical in shape, are red on an exanthematic background, which may be, according to the case, morbiliform or scarlatiniform, that is to say, composed of red areas of variable number scattered over the cutaneous surface, or having a rather dark red color. In some cases the exanthem may offer different characters on various parts of the body. The miliary papule is conical and its apex soon becomes white before collapsing. Between the papules or at other parts of the body small pearly pimples or tiny round vesicles appear; the latter contain a limpid serum. Desquamation commences in eight or ten days, first on the neck, then on the flanks—in other words, in the same order in which the eruption appeared. It usually takes place in large pieces, especially on the hands and feet. The period of convalescence is excessively long, and this is so even when there are no pulmonary or cardiac complications, which are indeed uncommon. The minimum duration of convalescence may be safely put at at least five to eight weeks, and it is accompanied by a very marked asthenia.

DIAGNOSIS AND PROGNOSIS OF THE AMNESIC ICTUS IN GENERAL PARESIS.

ALTHOUGH the diagnosis of an amnesic ictus is ordinarily easy when the loss of memory appears to be the only sign, this cannot be said to be true when it is accompanied by a certain degree of obtrusion of the other faculties. In these circum-

stances the amnesic ictus must be differentiated from the apoplectic, epileptic, or aphasic ictus, or even vertigo and stupor common in general paresis. In fact, all these phenomena bring about a sudden more or less profound intellectual obnubilation and this state might be thought to be the result of an important loss of memory. They differ, however, from the amnesic ictus in that all the faculties and not alone the memory are involved; there is even an absolute loss of consciousness in some cases. Likewise, the somatic signs—tinnitus aurium, visual disturbances, convulsions, paralyses, etc.—which accompany them, are not found in pure amnesic ictus. The vertigo, for example, offers sensorial disturbances. Usually the subject will present quite accentuated vasomotor disturbances of the face which sometimes becomes pale but more often red—even flushed. If the patient is standing he falls or avoids this by holding on to some object. There is no loss of consciousness, but for an instant, sometimes hardly perceptible, there is a diminution of the psychic activity which is made evident by a state of temporary bewilderment or intellectual confusion.

In amnesic ictus none of the foregoing signs are met with; the appearance of the patient does not change and only the bewilderment or curious questions suddenly put reveal the intellectual disorder. Amnesic ictus will hardly be mistaken for apoplectic ictus, as this state offers characteristic signs at the onset: the subject falls, there is absolute loss of consciousness, with absence of reflexes and sensibility, and occasionally convulsions. This state is sometimes accompanied by a rise of temperature which may last for several hours. It may happen that the apoplexy disappears quite rapidly, leaving the subject more or less amnesic, but this is not a true amnesic ictus because the amnesia here occupies only a secondary place, being merely an epiphenomenon in the evolution of a frank apoplexy. Epileptic ictus may also appear during the evolution of general paresis, rendering an appreciation of the intellectual state of the patient difficult to make. However, the aura and the involuntary automatic movements will lead to the correct diagnosis. Aphasic ictus may sometimes lend confusion, for besides being frequently accompanied by a certain amount of intellectual obnubilation, the few words the patient is still capable of uttering may lead the practitioner to suppose that there is quite complete loss of memory. After a manner, aphasic ictus might be regarded as a variety of the amnesic form because in reality there is a sudden loss of memory, either auditory, visual, or verbal, but more often it is motor aphasia with dysarthria which has a slow evolution and may even be permanent.

All these apoplectic, epileptic, aphasic, and vertiginous attacks were described by the older writers under the general heading of congestive attacks and in reality they are often accompanied by congestion of the face and ears. There is no doubt that amnesic ictus may be the consequence of more or less profound circulatory disturbances, and although the term ictus has not the merit of explaining the pathogenic mechanism which is still uncertain, it at least has the advantage of recalling the most important clinical character of the phenomenon—the suddenness of its appearance. Amnesic ictus appears to be much less frequent than other forms in the evolution of general paresis, perhaps because it is easily overlooked on account of the almost complete absence of physical signs. However, this may be, the types of general paresis with amnesic ictus appear to progress more rapidly and therefore have a darker prognosis than the forms without ictus.

ACUTE SYPHILITIC MENINGITIS.

THE term acute syphilitic meningitis should be applied especially to the acute meningeal accidents of the secondary phase of the infection, sometimes preceding, but more frequently accompanying the cutaneous lesions of this period. Meningeal accidents which merit the name of acute syphilitic meningitis, may be met with in hereditary syphilis. The acute meningitides of the tertiary period do not appear to have a distinctly syphilitic nature; they seem to be rather meningeal accidents due to some very ordinary cause, grafted upon a chronic meningitis.

The pathology of the acute type is essentially a meningoangiitis with hypersecretion of the cerebrospinal fluid. The treponema has been found only occasionally in the cerebrospinal fluid excepting in cases of hereditary syphilis. Lumbar puncture is absolutely necessary to confirm the diagnosis, because it will show a considerable hypertension, the presence of a large amount of albumin, and a marked lymphocytosis with plasma cells. The meninges are permeable to potassium iodide and the cerebrospinal fluid will also give a positive Wassermann, although the reaction of the blood serum may be negative. The lymphocytosis persists for a long time after the disappearance of the meningeal symptoms.

The onset of the meningeal symptoms may be sudden without prodromes, but generally insomnia and headache will be complained of long before the meningitis develops. When fully developed, acute syphilitic meningitis offers a clinical picture recalling that of tuberculous meningitis, but it differs from the latter by the fact that the symptoms are less distinct, by the absence of evident disturbance of the pulse and respiration, by its irregular evolution in successive outbursts and remissions, and finally and more particularly by the data given by the Wassermann reaction. A comatose form has been observed, likewise localized types, at the convexity with convulsions and epilepsy, or basal with paralyses of the ocular muscles.

The immediate outcome is rarely fatal, but the ultimate prognosis must be reserved. In the first place, after the symptoms of meningitis have passed

off, sequelæ are frequently met with—absence of the reflexes, the beginnings of the Argyll-Robertson symptom, and lymphocytosis of the cerebrospinal fluid. Secondly, quite frequently an acute meningitis may pass into the chronic type and it is now generally believed that chronic syphilitic meningitis is the causal factor of parasyphilitic accidents—tabes and general paresis—which considerably darkens the prognosis.

A prophylactic treatment, even when energetic, does not completely protect the syphilitic from meningeal accidents, whether mercury or one of the modern arsenical products is employed. Nevertheless, a prophylactic treatment should be carried out and systematically followed in every syphilitic subject whose cerebrospinal fluid presents a persistent lymphocytosis, even in the absence of any meningeal symptoms. The curative treatment of acute syphilitic meningitis requires in the first place free and repeated withdrawal of the cerebrospinal fluid; secondly, an energetic mercurial treatment. The arsenical products have a much more rapid action, but not a few observers advise against their use in nervous accidents on account of neurotropism, although Ehrlich attributed the untoward symptoms in these cases to the syphilis itself and not to 606.

The Myth of the Symbiotes.

Portier's description of his "symbiotes" or microorganisms which are indispensable for metabolism represents them as introduced originally from without but inhabiting the body cells and presiding over all biological synthesis. They are analogous histologically to mitochondria and chemically are identical with the vitamines of Funk. The theory is based on the study of certain phenomena which takes place visibly in low forms of life. The doctrine of symbiotes which was sketched briefly in the Medical Record about two years ago has called forth a volume by Lumière (reviewed in the *Gazette hebdomadaire des sciences médicales de Bordeaux*, December 14, 1919, xi, 36) which seeks to demolish it. The phenomena on which Portier was led to develop his theory are disputed and the symbiotes are apparently only highly resistent spores of saprophytes which lie latent but living in the midst of the tissues. They exist purely for themselves, are saprophytic and in no sense symbiotic. Lumière only rarely was able to cultivate these from the tissues and on various occasions he succeeded in cultivating some one of several familiar saprophytes from one or another organ of the frog or rat or other small animal. Evidently the tissues had been penetrated in some manner by the spores. From this standpoint the tissues are not always sterile, but unless there is cell death it is impossible to conceive how the spores can proliferate. In regard to mitochondria these have been known in vegetable histology since 1858, when Trecul described them, and forty years later they were rediscovered by Benda. These are known now to be albuminolipoid colloids and are radically different from the symbiotes which have a structure. In regard to the identity of symbiotes and vitamines both are destroyed by a heat of 120° C., while the melting point is much higher. But this dissociation of melting point and thermostability is found in a number of substances. If the symbiotes are vitamines then cultures of these saprophytes should be of value in avitaminoses; if they are of value it must be remembered that so is orange juice.

Treatment of Sea Sickness.

The resumption on a large scale of the ocean passenger traffic makes this subject rather timely. Dr. Cazamian discusses it in the *Bulletin générale de thérapeutique* for November, 1919, clxx, 17. He has devoted the past two years to the subject as visualized in the latest developments of science. Quite inevitably seasickness must be restudied in the light of endocrinology and the pathology of the sympathetic. The author has studied over 50 seasick people and finds that in the fully developed *status naupathicus* the arterial tension is increased. However, the tension drops while the illness is still present. The oculocardiac reflex was inverted in most patients, but pressure in the pit of the stomach usually accelerated the pulse. The spinal fluid obtained by puncture showed no constancy while the blood counts were within normal limits. The author found a prevalence of sympathicotonia attributable to hyperadrenia, although Naame had reported the exact converse—vagotonia from hypoadrenia. This disparity probably means that initial sympathicotonia passes eventually into the opposite condition or, more accurately, that stimulation of the adrenal cortex leads in time to exhaustion of the same. Certainly seasickness is largely a matter of adrenal-autonomous pathology. Crises of vomiting are vagotonic—paroxysmal vagotonia. But the sympathicotonic is naturally predisposed to seasickness, just as the vagotonic enjoys some immunity. The young child, being naturally vagotonic, is immune. From this angle treatment is simple. The vagotonic paroxysms of vomiting and other critical manifestations are relieved by hypodermics of atropine, 1 or 2 mgm., and the other vagotonic standby—adrenalin—is a valuable synergist whenever there is a condition of hypoadrenia. If the tension is up adrenalin aggravates. It is better to give suprarenal extract by the mouth in these cases than to inject adrenalin.

Eczema as a Defence Reaction.

Eczema appears to be largely a reactive phenomenon and the reaction is placed by Gougerot (*La Médecine*, November, 1919, i, 2) under defence reactions. It appears to make no vital difference whether the irritant which causes the reaction acts internally or externally, save that in the former case some predisposition which we call diathesis is at work. If the irritant is from within, it is a toxic substance which the organism is trying to be rid of and thus we may use the expression defence reaction. All of the emunctories of the body may show irritation accompanying eczema and there is also evidence that the toxic substances seek escape through unaccustomed channels. The skin lesions appear to be due to attempts at escape through the integument. At times the sole manifestation is

pruritus, at other times there may be fugacious eruptions like urticaria, and finally there is a well marked sterile dermatitis which we call eczema. The author explains the frequent association between eczema and obesity as follows: certain foreign toxic material is not eliminated, but is magazined in the subcutaneous tissues. It may here give rise, as in eczema, to edema, while, in other cases, it stimulates the fatty cells of the same area to store up fat. This view is analogous to an old doctrine of Bunge's that all fat is of toxic origin and akin to the fatty metamorphosis of the liver cells in poisoning by phosphorus, arsenic, and antimony.

News of the Week.

Government Needs Physicians. — The United States Civil Service Commission announces that a large number of physicians are needed for employment in the Indian Service, the Public Health Service, the Coast and Geodetic Survey, and the Panama Canal Service. Both men and women will be admitted to examinations, but appointing officers have the legal right to specify the sex desired when requesting the certification of eligibles. Entrance salaries as high as $200 a month are offered, with prospect of promotion in some branches to $250, $300, and higher rates for special positions. Further information and application blanks may be obtained from the Secretary of the U. S. Civil Service Board at Boston, New York, Philadelphia, Atlanta, Cincinnati, Chicago, St. Paul, St. Louis, New Orleans, Seattle or San Francisco, or from the U. S. Civil Service Commission at Washington, D. C.

Red Cross Aids in Influenza Epidemic. — Red Cross chapters throughout the country are cooperating with the local boards of health, and in communities where no regular health organization exists the Red Cross has taken charge of the situation independently, where influenza conditions warrant. Women are busily engaged in the workrooms making masks, hospital garments, and other articles needed by the doctors and nurses in fighting the epidemic. The Red Cross Motor Corps are working on a war-time basis, moving pneumonia, influenza, and whooping cough cases to and from hospitals. Some chapters have installed diet kitchens. In New York City more than 12,600 articles were supplied within three days. At the request of Health Commissioner Copeland the Red Cross opened a bureau for the registration of nurses in the Health Department's offices, where nurses were interviewed and assigned to cases. The New York County chapter placed at the disposal of the Board of Health its file of nurses, attendants, and trained and volunteer aids. Volunteer investigators were also furnished for the different health zones. In Chicago, 14,000 women, trained by the Red Cross during the war, were called to service to aid in checking the epidemic. These and many other activities on the part of the Red Cross have been of incalculable aid to the local health authorities whose normal resources were generally inadequate to meet the emergency.

A French Treatment of Influenza.—A dispatch to the *Sun* from Paris gives details of a remedy for influenza advised by Dr. de Gerin of that city. It consists of the injection into the gluteal muscles once a day for five or six days of a solution of guaiacol, 0.1, eucalyptol, 0.5, and camphor, 0.5, in 3 c.c. of sterilized olive oil. If pulmonary complications appear, he gives a tablespoonful every two hours day and night of a mixture of tincture of opium and tincture of belladonna, of each 35 drops, and ammonium chloride, 4 grams, in 250 c.c. of distilled water, flavored with simple syrup, 75 c.c., and syrup of orange flowers, 25 c.c.

French Medical Society Resumes Meetings.—La Société Française d'Histoire de la Médecine has resumed its monthly meetings at the Faculté de Médecine, Paris, the first meeting of the season having been held on October 4. The society is planning the establishment of a museum of the history of medicine, and appeals to its members for constributions. The *Bulletin* of the society will be issued early this year. Communications and manuscripts may be addressed to M. Fosseyeux, No. 3, Avenue Victoria, Paris.

Mobile Hospital Sent to Roumania.—A mobile hospital, known as the "Auto-Chir," purchased by the American Red Cross for the American Expeditionary Forces at a cost of $400,000, has been sent to Roumania. The Auto-Chir consists of an *x*-ray truck, an electrogenic group with accessory parts, a heating plant, an operating room with plate glass cabinets equipped with surgical instruments, ambulance trucks containing beds for twenty patients, tent hospital trucks, an acetylene truck for lighting the hospital, and storeroom trucks with all manner of supplies. There is also a large truck containing sleeping rooms for doctors, nurses, and internes. This unit is now functioning near the Roumanian Army.

Influenza Rages in Poland.—According to American Red Cross reports the medical authorities are baffled by the virulent form of influenza which now scourges Poland. The suddenness of the attack and the high percentage of fatalities are the distinctive features of the epidemic. Hundreds of deaths occur daily in Warsaw, while three-fourths of the hospital attendants have been stricken.

Influenza on Spanish Liner.—Thirty-five cases of influenza among passengers and crew of the Spanish steamship *De Satrustegui* were reported when she arrived at New York recently. The boat was held in quarantine and the serious cases were sent to Swinburne Island.

Dr. Abr. L. Wolbarst has resumed his genitourinary clinics, on Thursday evenings, at 8:30 o'clock, at the West Side Dispensary and Hospital, 328 West 42nd Street, New York City.

American Scholarships for Foreign Students.—Under the fellowships offered by the Rockefeller Foundation students from the following countries are now attending American medical institutions: Czecho-Slovakia, 4 physicians; China, 8 physicians, 8 undergraduate medical students, 4 nurses, and 11 medical missionaries on furlough; Brazil, 4 physicians; San Salvador, 1 physician.

Hospitals for the Insane Overcrowded.—According to a report made to Governor Smith of New York by State Commissioner of Health Her-

man M. Biggs and Dr. Pearce Bailey, chairman of the Commission for Mental Defectives, overcrowding exists in Central Islip, Brooklyn, and Manhattan State Hospitals for the Insane. In one ward at Central Islip with a normal capacity of 187 patients, the actual number found in the ward was 400. At the Brooklyn State Hospital there were 1,177 patients, although the normal capacity is only 637. The report also called attention to the shortage of help because of the small pay received by the attendants. As a result of the investigation covered in this report the Governor has appealed to the Legislature to extend the hospital facilities and to give proper increases in pay to the hospital help.

Diseases Under Investigation.—The Hospital of the Rockefeller Institute for Medical Research announces that a limited number of patients suffering from measles will be admitted to the isolation wards, and that it will receive patients suffering from acute lobar pneumonia and other acute respiratory infections, cardiac disease, acute rheumatic fever and nephritis.

Medical Society of the State of New York.—The annual meeting of the Medical Society of the State of New York will be held in New York City, March 23-25. The House of Delegates will meet on Monday afternoon, March 22, in Hosack Hall, New York Academy of Medicine, 17 West 43rd Street. The scientific sessions, which will begin on Tuesday afternoon, will be held at the Waldorf-Astoria and the Hotel McAlpin.

Georgia Medical Society Honors Service Men.—The Fulton County Medical Society held a banquet January 9 in honor of its members who were in service during the world war. More than 200 members attended.

Government Positions in Occupational Therapy.—The United States Civil Service Commission, Washington, D. C., has announced examinations for field supervisor of reconstruction aides in occupational therapy; superintendent of aides in occupational therapy; special instructor in occupational therapy; and reconstruction aide. Both men and women are eligible. Examinations for field supervisor and superintendent will be held on February 24; the dates of other examinations will be announced later.

Medical Department of American Legion.—The Medical Department Post of New York of the American Legion was organized at a meeting held at the New York Academy of Medicine, January 12. A constitution and by-laws were adopted. It is proposed to gather into this post all medical officers and enlisted men now residing in New York county who served in the medical department during the World War.

Liquor Stations Favored.—Dr. Royal S. Copeland of the Department of Health of New York City, following a suggestion made by the Bronx Pharmaceutical Association, announced that he would endeavor to ascertain whether the Treasury Department would not take steps toward the immediate establishment of Government stations about the city for the dispensation of whiskey and brandy for medicinal purposes. Only ten per cent. of the druggists of the city, according to the Commissioner's statement, have taken out licenses which will allow them to dispense medicinal whiskey and brandy on the presentation of prescriptions from doctors.

To Standardize Hospitals.—A meeting of the Greenville County (S. C.) Medical Society was recently called for the purpose of formulating plans for the standardization, in accordance with the rules and regulations of the American Medical Association, of all the hospitals in and around Greenville. Representatives of the hospitals, nurses, city officials, and representative citizens cooperated with the medical society in the plan.

Medical Society Advocates Committing Drug Addicts.—The Shawnee County (Kan.) Medical Society at a recent meeting held in Topeka adopted a resolution endorsing special legislative provisions for the committal of drug addicts in Kansas to the State hospital for treatment.

Leprosy in Boston.—A case of leprosy was discovered in Boston recently in an unmarried male, 23 years of age, who was a chocolate factory worker. He will be sent to the State leper colony on Penikege Island.

Death From "Sleeping Sickness."—A young man of nineteen, who was recently sent to St. John's Riverside Hospital, Yonkers, N. Y., after having consulted a physician on account of headache, lapsed into a sleep from which he did not awake. The death certificate gave encephalitis lethargica as the cause of death.

Osteopaths Cannot Vaccinate in Pennsylvania.—Deputy Attorney General D. J. Myers of Pennsylvania, recently rendered the decision that "osteopaths have no right to vaccinate nor issue certificates therefor, nor have they the right to issue certificates setting forth that a child has been properly vaccinated or vaccinated in accordance with the regulations of the Department of Health."

New Totals of War Deaths.—In a supplementary report to the Budget Committee, Louis Marin, member of the French Chamber of Deputies, has compiled from official sources the losses of human life caused by the war. The French Army had lost at the date of the armistice 1,334,400 men. Since the armistice 600 officers and 28,000 soldiers have died in French hospitals as the result of wounds and diseases. This represents 16.44 per cent. of the effective mobilized forces. From start to finish, 4,988,213 such wounded were treated in hospitals. The French naval forces lost 10,525 men. M. Marin also gives the losses in the Allied armies in killed, missing, and traced among prisoners, as follows: Belgium, 44,000; United States, 114,000; Great Britain, 869,000, of whom 682,000 were from the United Kingdom; Greece, 12,000; Italy, 490,000; Rumania, about 400,000, including prisoners alive; Russia, 1,290,000 (the statistics from October, 1917, are untrustworthy), and Serbia, 297,000. Germany's killed and missing total 2,041,000; Austria-Hungary, 1,542,817; Bulgaria, 101,224, and Turks, 325,000 killed.

Economic Loss from Tuberculosis.—According to a statement by Dr. Herman M. Biggs, Health Commissioner of New York State, the economic loss in 1918 from tuberculosis in New York was $81,576,000, a greater loss than from any other disease. There were 10,197 deaths from tuber-

culosis in various forms in the State last year. Most of the victims die between the ages of 15 and 50, or at an average of 35 years, thus losing seventeen years which would ordinarily be employed in productive work. The death rate from pulmonary tuberculosis, according to Dr. Biggs, has been decreased from 236 per 100,000 in 1898 to 150 per 100,000, the figure for 1918. The Red Cross Christmas sale campaign cooperated with other agencies this winter in the sale of Christmas seals to lessen this drain on New York's resources.

Dr. Richard Clarke Cabot, Professor of Clinical Medicine at Harvard Medical School and chief of the West Medical Service of the Massachusetts General Hospital, has been appointed Professor of Social Ethics at Harvard College. Dr. Cabot enters at once upon his new duties, at the same time continuing his present connections.

Dr. Mary E. Mosher, of Roxbury, Mass., was recently elected president of the Massachusetts Surgical and Gynecological Society. She was one of the first women to be admitted to membership in the society and is the first to hold the office of president.

Dr. J. M. T. Finney, Associate Professor of Surgery, Johns Hopkins University Medical School, has declined an invitation to fill the chair of surgery in the Harvard Medical School.

Dr. Burton Peter Thom has been appointed assistant visiting physician to the Workhouse and Penitentiary Hospitals, Blackwell's Island, New York City.

Dr. Abraham Jablons of Brooklyn, N. Y., formerly Lieutenant Medical Corps, U. S. Navy, having been released from duty at the Navy Yard, New York, has been appointed Medical Inspector, Bureau of Child Hygiene, Department of Health, City of New York.

Medical Society Elections.—The HENNEPIN COUNTY (MINN.) MEDICAL SOCIETY, at its annual meeting held January 5, elected the following officers for the ensuing year: *President,* Dr. J. Frank Corbett; *First Vice-President,* Dr. Angus Morrison; *Second Vice-President,* Dr. F. L. Adair; *Secretary-Treasurer,* Dr. C. W. Petit (re-elected).

Obituary Notes.—Dr. JOHN BOSLEY, Lieutenant-Colonel, U. S. Army Medical Corps, retired, died January 8 at his home in New York City. He was a graduate of Johns Hopkins in 1901.

Dr. NEIDHARD H. HOUGHTON, of Boston, Mass., died at the Homeopathic Hospital in that city, December 26, as the result of being struck by a street car on the day of his death. He was 58 years of age. He was graduated from the New York Homeopathic Medical College in 1887. He had practised for many years in Boston, and was a lecturer in the Boston University School of Medicine.

Dr. CHARLES RUSSELL CAVANAGH, of Boston, Mass., died December 25. He was graduated from the Medical School of Harvard University in 1892, and received his hospital experience at the City and Carney hospitals, in Boston.

Dr. FRANKLIN BENNETT, of Brooklyn, N. Y., died from pneumonia December 21, in his seventy-first year. He was graduated from New York University Medical College in 1875, and had practised in Brooklyn for forty-two years.

Correspondence.

THE TREATMENT OF INFLUENZA.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In the MEDICAL RECORD of January 10, 1920, received to-day, I find an article entitled "Treatment of Influenza by an Apparently Specific Method" by Dr. Francis E. Park of Stoneham, Mass. I have found nothing better than the mixture I have previously recommended, consisting of ammonium salicylate, gr. lxxii; caffeine, gr. vi; essence of pepsin, ℥i; water, ℥vi. Of this I at present give a tablespoonful every hour for three or four hours, and thereafter a desertspoonful. For convenience sake in many cases I give the remedy in capsules instead of solution, and I then omit the pepsin. At bed-time I give aromatic spirit of ammonia and sweet spirit of nitre. I then stop the salicylate mixture. If there is cough and fever I start warm creosote inhalations from a croup kettle, with or without compound tincture of benzoin. I use the benzoin only when objection is made to the smell of creosote.

There is no specific against influenzal pneumonia, but what I have outlined will help prevent it in a measure and will greatly modify its seriousness many times. Good whiskey, black coffee, and strophanthus in small repeated doses will save life, if any treatment will.

Fear of contagion is a bugbear which should not be tolerated. It is lack of knowledge which makes it prevail. Personal immunity is something the wisest physicians do not as yet understand; I mean the why and wherefore.

I hope you will find space for this letter at the present time when a dependable treatment for influenza is so much needed.

BEVERLEY ROBINSON, M.D.
42 WEST THIRTY-SEVENTH STREET, NEW YORK.

OUR LONDON LETTER

(From Our Own Correspondent.)

LONDON, Jan. 16, 1919.

Radium and Cancer.—At the Middlesex Hospital in London cancer research work has been going on for many years and the investigations have been productive of much useful knowledge in this direction and particularly so far as treatment is concerned. During the war and ever since the armistice cancer research work at the Middlesex Hospital has been greatly handicapped by lack of funds. However, research with regard to the effects of the *x*-rays and radium has been continued. Recently a magnificent loan has been made by the British Government to the Middlesex Hospital Laboratories. This loan consists of five grams of radium bromide and a feature of this acquisition is that although the quantity is less than one-fifth of an ounce, it is the largest that has ever been available for use in bulk in the work of research. It may be said that its value is in the neighborhood of £100,000, and the loan is made subject to termination at ten days' notice in case the Government should need it. The radium at the time of the armistice was in the hands of the Ministry of Munitions and because it

was no longer required for the manufacture of gun-sights and other articles of which luminosity at night is an essential feature, Mr. Cecil Lyster of the Middlesex Hospital Cancer Research Department, was consulted as to its disposal. Mr. Lyster fully recognizing the great therapeutic potentialities of so large an amount of radium, suggested that if it were lent to the Middlesex Hospital in one parcel it would render possible developments hitherto hardly dreamed of by the most enthusiastic investigator. The authorities fell in with Mr. Lyster's suggestion, and it seems likely that in the future the Middlesex Hospital Cancer Department will make marked progress in cancer research and treatment.

The Ministry of Health and Its Consultative Medical Committees.—There are four consultative medical committees, or councils as they are termed in the act, in connection with the Ministry of Health. It is hoped and intended that they will discharge the function of reconciling medical and public views on health administration. In short, it is meant that they should insure that the existing State medical service, acting under permanent officials shall cooperate for the prevention, control, and abolition of disease with medical practitioners, consultant or general and whether engaged or not in panel practice. Three councils have been instituted for England and Wales, one on medical and allied services, one on national health insurance, and one on local health administration. The fourth council is for Wales. The English Consultative Council on Medical and Allied Services is the one whose particular province is to deal with the immediate problems of medical practice and it has been constructed with this object in view. Already I have drawn attention to the ingenious way in which its members have been selected, but will briefly run over the list again. Among its twenty members it includes consultants of high rank as physicians, surgeons and obstetricians; two distinguished medical women; two well-known medical officers of health and a prominent anatomist, a skilful and learned chemist, and a biochemist of no mean repute. In addition to these are the secretary of the largest metropolitan hospital; the Registrar of the Pharmaceutical Society of Great Britain; four medical men of weight with insurance and panel committees; and the chairman of Council and the Treasurer of the British Medical Association. To this body will be referred all the problems which arise in the working of the Ministry of Health, when the national development and extension of medical, nursing, and midwifery work are taken into consideration. Moreover, this Council possesses the power, especially when the nursing and midwifery arrangements are in question, to form committees by the cooptation of persons outside the Council. The scheme appears to be designed admirably, but of course it is not known as yet what the real influence of the Council may be. After all, it is only an advisory council, of which the Minister, if he thinks fit, may not seek advice and he may seek it and yet may not take it. Politics and expediency may prove stronger than the best interests of the people or the Minister may deem that he is the best judge of what is good for the nation.

Panel Practice.—The members of the British medical profession are at the present time considerably exercised in mind with regard to the position of panel practice. Certain new regulations have been brought forward and considered and have been received with very mixed feelings by the profession. Some medical men are whole heartedly in favor of the regulations, others are unalterably opposed to them, while yet others are in a state of almost indifference. The matter of national insurance legislation will be discussed fully in a subsequent letter, but this much may be said, that although the Consultative Medical Council will not necessarily be asked to advise directly concerning the situation, the views of its members will undoubtedly be presented to Dr. Addison and his lieutenants, Sir Robert Morant and Sir George Newman. In considering the probable outcome of the deliberations regarding panel practice, it must always be borne in mind that the final decision by no means rests with the Medical Consultative Council, or rather the advice of the Council is not the only advice which will be tendered to the Ministry of Health. The Council on National Health consists of the Friendly Societies, which powerful bodies are as interested as the medical profession in securing the good care of the public health. But the Friendly Societies do not see eye to eye with medical men and, in fact, in the past there has been a certain amount of antagonism between them. They have not the same reasons as the doctors for disliking or mistrusting the panel regulations. The Friendly Socities wield an immense political influence and their wishes will consequently be treated with every consideration by the powers that be.

Medical Degree Proposed for a Bone-Setter.—A petition in favor of a medical degree honoris causa being granted to Mr. H. A. Barker has been signed by over 300 members of the present and former House of Commons. The memorial states that during the war "Mr. Barker was the means of removing the disabilities of many men whose services would otherwise have been lost to the nation" and that "the case is eminentiy one for favorable consideration, in view of the unique and distinguished services Mr. Barker has rendered to suffering humanity and the cause of science through a long period of opposition, contumely, and persecution." Mr. Barker is of course the well-known "bone-setter" and is one of those men who have a remarkable, almost instinctive, manipulative skill. His reputation is international. A few years ago he paid a visit to America.

Memorial to Lord Lister.—In order to perpetuate the memory of Lord Lister it is proposed to establish in Edinburgh an institute in which the scientific investigation of disease can be undertaken. Such would be a fitting memorial to the man whose discoveries were the results of research, and it is to research and the teachings of its results that this memorial is to be dedicated. In a statement recently made by the University of Edinburgh and the Royal College of Physicians and Surgeons of Edinburgh it was announced the need for such an institute was pressing. It is further stated that a site has been secured close to the Edin-

burgh Royal Infirmary and the medical school of the University, at a cost of over £50,000. To pay for the site and to erect, equip, and maintain the necessary buildings £200,000 will be required. The University and the Royal College of Physicians and Surgeons have agreed to contribute £25,000 and a committee has been formed to launch a public appeal. Mr. Balfour, Chancellor of the University, has consented to act as honorary president and the honorary vice-presidents are the Duke of Atholl, Lord Roseberry, Lord Beatty, Lord Glenconner, Lord Leverhulme, and Sir J. Lorne McLeod.

An American Surgeon for an East London Hospital.—Mr. Philip Franklin, F.R.C.S., has recently been appointed surgeon in charge of the throat and ear department of the East London Hospital for Children. Mr. Franklin, who is of American parentage, has been especially energetic in initiating and promoting the "Fellowship of Medicine" of which he is an honorary secretary. He is also organizing the new American Hospital and Club in London.

Obituary.—Sir Thomas Richard Fraser, M.D., F.R.C.P., Emeritus Professor of Materia Medica and Clinical Medicine in the University of Edinburgh, and Physician in Ordinary to the King in Scotland, died in Edinburgh on Jan. 4 in the seventy-ninth year of his age. Thomas Fraser early exhibited his scientific bent by obtaining at the age of 21 the gold medal for his graduation thesis "On the Characters, Actions, and Therapeutic Uses of the Ordeal or Calabar Bean." He became assistant to Sir Robert Christison, the most famous Professor of Materia Medica Edinburgh University ever had. In 1877 he was appointed Professor of Materia Medica in succession to Christison. Fraser was one of the leading pharmacologists of the world, and his work in cooperation with his colleagues has gone a long way toward establishing the drug treatment of disease upon a scientific basis.

Perhaps, the particular direction of Fraser's work with which his name will be most closely associated is that having to do with his investigations into snake poisoning. He and Calmette were the pioneers in the discovery of a serum treatment for snake poisoning. In 1894 Calmette published an account of extended researches into the production of immunity against snake venom among animals subjected to experimental infection and in 1895 Fraser published a description of the antidotal properties of the blood serum of immunized animals and of venomous serpents and in 1896 he published an account in the *British Medical Journal* in which he directed attention to the limitations of the antidotal powers of antitoxin as illustrated in the antagonism between antivenene and snake venom. Fraser enjoyed an international reputation and was the recipient of numerous academic honors. Although in failing health he carried on his work as professor up to the summer of 1918 when Professor A. R. Cushny succeeded him in the chair of Materia Medica of the University of Edinburgh. One of his sons is a physician in New York, and at the present time is serving with the American Army on the Rhine.

OUR LETTER FROM GENEVA.

(From Our Own Correspondent.)

GENEVA, Jan. 15, 1920.

Infant Feeding in Vienna.—Since Austria has been making frantic appeals for food, particularly for Vienna, it may be interesting to note the results of infant feeding obtained by some Austrian physicians, among others Müller and Czerny, during the last two years of the war and still more recently. It is quite certain that they have had the opportunity of observing infant feeding reduced to its simplest expression, but they point out that the reduction of alimentation of infants has not resulted in such bad conditions as might be supposed, because in time of peace too much milk was given. A daily ration of from 250 to 500 c.c. of milk in children over one year of age has given excellent results. Milk is wanting in certain necessary substances, and it was for this reason that Heubner long since advised adding green vegetables to the diet of children in the second year, since they are rich in iron and lime salts. The Austrian physicians do not think that there is any valid reason for giving extra rations of milk because such an addition does not compensate the deficit of meat and fat. Many pale infants are not necessarily anemic. Their blood is normal, their paleness being due to other causes—pseudoanemia. In these subjects there is a decreased percentage of hemoglobin. The total quantity of blood as well as the relative amount in play with each cardiac contraction, are not diminished; therefore, there is no oligemia.

Pseudoanemia.—Müller describes three types of pseudoanemia. First, neuropathic infants with disturbances of the equilibrium of the vegetative nervous system due partly to the vagus, partly to the sympathetic. In pathological cases the sympathetic is the most important, since it gives rise to exaggerated contractions of the smaller vessels, hence the pale skin. These subjects often have very brilliant eyes with dilated pupils, reacting sharply to all pathogenic influences. Such subjects may become really anemic so that caution in diagnosis must be exercised. Second, there is a class of children whose blood is irregularly distributed throughout the body in diseases which produce congestion of the various viscera, the liver and intestines in particular, and so withdraw the blood from the surface, hence pseudoanemia of alimentary origin. The third category comprises pseudoanemias due to the texture of the skin in highly pigmented subjects or when the capillaries of the dermis are undeveloped, or to infiltration of the skin in lymphatic or hydropic children. The pathogenesis of the so-called "school anemias" is not quite clear, and they probably belong to the first category or else they are true anemias due to tuberculosis, influenza, or post-diphtheritic—otherwise anemia from toxi-infection. The methods for surely recognizing true anemia, such as the estimate of the total mass of blood, total hemoglobin, size of the heart, and relative amount of blood, are technically difficult to carry out. Paleness of the integuments and mucosæ, and the percentage of hemoglobin are the best off-hand diagnostic signs. In cases with pale mucosæ and normal percentage of hemoglobin the diagnosis

of oligemia should be made. Too little blood passes through the arteries. What is still more important are functional cardiac murmurs and anemic souffles. The former denote the attempt made by the heart to compensate extreme dilatation which may reach even insufficiency of the volume of blood of the ventricular systole. The estimate of the hemoglobin and the red blood cell count will give the globular value. Of the three techniques of hemoglobin fixation due to Tallquist, Plesch, and Sahli, the latter is the best. The normal percentage for a child is 75 per cent.

Alimentary Anemia, long known, has been regarded until recently from the viewpoint of etiology as the result of too little iron in the food. When cow's milk forms the principal part of the child's diet, it is likely that the amount of iron contained in the rest of the food ingested is insufficient. Czerny has given a broader conception to alimentary anemia, since with it he includes anemia with enlarged spleen—pseudcleucemic anemia and the splenomegaly of rickets—on account of the therapeutic success obtained by removing milk from the diet. This fact eliminates the special nosographic character of splenic anemia. A marked reduction of hemoglobin, as low as 20 per cent., is observed, and often small diminution of the red corpuscles and a globular value below 1. Often the staining and shape of the red cells have changed, and even nucleated red cells are occasionally found. The neutrophile leucocytes drop to 16 per cent., hence a relative lymphocytosis. Most of these subjects are fat with a yellowish skin. Occasionally, but rarely, some are met with who are emaciated. Czerny does not attribute this type of anemia to a want of iron but to the fat in milk and to the fatty acids which do not split up in the organism. If milk is replaced by some other diet—green vegetables—a favorable turn will be seen by the aspect of the child.

Toxic Anemias.—The second group of cases has been studied by Müller. Their etiology is toxi-infection—tuberculosis, syphilis, influenza. Syphilitic anemia is encountered in children with luetic visceral lesions, with bone involvement, especially in infants. In older syphilitics the anemia is due to intoxication and offers a relative lymphocytosis. Tuberculous anemia is met with when the lymphatic system is involved and is peculiar to children, and "school anemia" is decidedly in this class. A relative polynucleosis is a symptom of great value for the differential diagnosis. Post-influenzal anemia and its sequelæ—empyema, pyelonephritis—gives rise to a decrease of hemoglobin and a large number of polynuclears. All children improperly fed, as well as syphilitic and tuberculous subjects, do not necessarily become anemic, as these conditions merely represent predisposing factors to anemia. Chlorosis affects the female sex; the hemoglobin is greatly diminished, the red cells not so much so, consequently the globular value is low. According to Schmidt and Plesch, the total quantity of blood in these cases usually increases to twice or thrice its bulk, while the clinical symptoms are those of a relative increase in the quantity of blood. The treatment is above all to be directed to the pathogenesis—syphilis, tuberculosis, influenza, etc.

A mixed diet is indicated for pseudoanemia without exaggerating the amount of albumin ingested. Iron does no good, as it is in normal amount in the organism. The treatment of infantile tuberculosis needs no comment, likewise that of the convalescence from influenza, etc. In alimentary anemia the ration of milk should be decreased and the amount of ferruginous foods increased. Often, according to the Vienna physicians, one-half liter of milk daily is too much and 100 c.c. with a mixed diet has been found satisfactory. At the beginning of the second year meat and sausage are given. Whether the Anglo-Saxon infantile intestine would proclaim a strike with such a diet is a question that has not been—and probably never will be solved.

Progress of Medical Science.

1. The Origin of the Intrapelvic Treatment of the Stump after Supravaginal Hysterectomy for Fibroid Tumor of the Uterus.—J. Riddle Goffe traces the history of the operation in question, which was first performed by him on May 26, 1888. The history of the patient upon whom it was performed is reviewed and the technique of the operation described. The method was then entirely novel and original, embracing new untried features and meeting all the requirements of a perfected surgical procedure. First and foremost, it solved the problem of dropping the pedicle and closing the abdominal incision without drainage. Secondly, it covered all raw surfaces. Third, it fastened the infundibulopelvic and round ligaments to the stump, thus giving support to the pelvic diaphragm. And lastly, it restored the pelvic organs to their normal positions and relations in the pelvis, disposing of the traumatic tissue with the nicety of a plastic operation. All this the writer pointed out in his first paper describing the operation, which was presented before the Obstetrical Section of the New York Academy of Medicine in March, 1890, and published the following month in the *American Journal of Obstetrics and Diseases of Women and Children.* Four cases were reported in this paper. In September, 1892, Dr. Baer, of Philadelphia, read a paper before the American Gynecological Society in which he reported ten cases of fibroid tumors, with one death, operated upon by him by what he claimed was an entirely new and original operation. On careful analysis the operation, in its essential features, was the Goffe operation, modified by systematically transferring the main ligature from the cervix to the uterine vessels in the broad ligaments—a refinement of technique but not essential to the procedure. The operation has come to be known as the Baer operation, believed by many to have been invented by him, despite the fact that in addition to the writer's original communication, other papers antedated that of Baer. In the discussion of Baer's paper Dudley claimed to have been "talking of this method two years before Dr. Goffe read his paper," and to have performed the same operation in 1884, in California, with the exception "that the double ligature which was put around the stump was not covered by the peritoneum." No report was made of this operation, and consequently the writer holds that it has no bearing on the priority of the procedure. After reviewing the work of European surgeons he was convinced that the operation is purely American—the product of American ingenuity, courage, forethought, prudence, patience, and persever-

ance. It has superseded all other operations in every country, and stands to-day without a peer as the *operation par excellence.*

13. Gall-bladder Disease: Summary of Four Hundred and Twenty-five Cases Treated at the Hartford Hospital From 1914 to 1918. A. W. Branon.

7. Late Results in the Radium Treatment of Cancer of the Uterus.—J. Louis Ransohoff reports that in a series of 32 cases treated 19 per cent were free from recurrence for from two and one-half to five and one-half years; one patient for five and one-half years; two patients for over four years; one patient for three years, and one for two and one-half years. This percentage of cure may seem small, but it compares favorably with that following operation. Deducting eight cases in which the treatment was incomplete raises the percentage to 25. The remaining twenty-six patients are either known to have died of the disease, or have at present a recurrence, or can not be traced. From his observation it would seem that the results were the same whether the radium treatment was or was not preceded by curettage or the cautery, therefore he had given up both curettage and cauterization as preliminary to radium treatment, depending entirely upon the radium. If the cases for radium treatment were chosen with the same degree of care that they are chosen for operation, the percentage of cures, in the writer's opinion would be very large. There is scarcely any case so far advanced that some improvement may not be obtained from radium treatment. In this work it should be the province of all observers not to work for statistics, but to give every patient a chance, if not for a cure, at least for an amelioration of symptoms. He expresses the view that radium treatment should entirely supplant operation, not only in the treatment of inoperable cases, but also in the treatment of operable cases of cancer of the cervix.

6. On the Removal of Large Cervical Tumors, Occupying the Vagina.—J. F. Peart reports the removal, by laparotomy, of an intravaginal fibroid which, when depleted of blood, measured 5 in. by 3½ in. and weighed 10 oz. He considers that he was justified in performing laparotomy, and that the abdominal route is to be preferred in such cases. The following essential factors seem to be often overlooked: 1. The frequency of associated pathological conditions of the corpus uteri and adnexa, which can be dealt with only by laparotomy; 2. the possibility of malignant degeneration in an intra-abdominal associated growth; 3. the practical impossibility of diagnosing the presence of such conditions in most of these cases, for a bimanual examination cannot be carried out. The objection that may be urged will no doubt be the relatively greater danger to the patient of the abdominal operation, but in the present days of aseptic surgery there is little to be feared if the operator is accustomed to abdominal work.

4. The Relation of Pfeiffer's Bacillus to Influenza.—Stanley Wyard gives his conclusions regarding the etiology of influenza based upon a study made during the 1918 epidemic. Attempts were made to obtain cultures from the circulating blood in three cases, and from the heart's blood *post mortem* in two. Of the former, two were sterile and one yielded streptococci; of the latter, one was sterile and one gave streptococci. In no case was Pfeiffer's bacillus discovered, and of three swabs taken from the nasopharynx none showed this organism. Cultures were made from the sputum in seventy-three cases, the specimens in all cases being purulent or mucopurulent in character. The *Bacillus influenzæ* was recovered seventeen times (24 per cent). From his studies Wyard holds that influenza is not produced by Pfeiffer's bacillus, but by some other virus at present unknown, since—1. The *B. influenzæ* is found in only a proportion of the cases. Other workers have, however, recovered it in more than 90 per cent, but streptococci can be found in quite as many. 2. In certain epidemics of influenza it has been found extremely rarely, while in others it has been found entirely absent. 3. It is found in cases other than influenza. 4. No specific immunity has been demonstrated to follow infection with this organism. Here again, however, others have arrived at a different result, and have found agglutinins to the bacillus in certain cases of influenza, but their presence has been found by no means constant, and they appear more frequently in the first week of the disease than in the later stages. The observation that the bacillus is pathogenic to animals after intracerebral injections is held to be no proof of an etiological relationship with influenza, since in the human disease infection can never be effected by that path; while equally invalid in this respect is the fact that it has been recovered from pleural, arthritic, and meningeal exudates. It is well established that certain organisms—for example *B. coli communis*—though normally harmless saprophytes, may in certain circumstances become pathogenic; and it is probable, or even certain, that the *B. influenzæ* Pfeiffer is one of these.

2. An Analysis of Cases of Uterine Fibroids Treated by Abdominal Subtotal Hysterectomy.—Raoul Seheult, Resident Surgeon, Colonial Hospital, Trinidad, says the records of the Colonial Hospital, which provides accommodation for 320 beds, show that 7,141 female patients (excluding those treated in the maternity and tuberculosis wards) were admitted during the five years ended March 31, 1916, and of these 113, or 1.5 per cent., were subjects of uterine cancer, and 241, or 3.2 per cent., of fibroids of the uterus. The admissions to the

female wards were practically confined to black, colored, and East Indian women. In view of the frequency of uterine fibroids in the colony and the apparent proneness of the negro race to this affection, an analysis of 130 consecutive cases treated under his care by abdominal hysterectomy from February, 1911, to April, 1917, were reviewed. The cases fall into three groups: (1) hysterectomy with conservation of the ovaries; (2) hysterectomy with removal of one ovary; (3) hysterectomy with removal of both ovaries. In the 93 cases that he was able to trace, with an observation period ranging from two to seven years, the after-results are reviewed with regard to general health, continuation or cessation of menstruation, artificial menopause, effects on sex instincts, and condition of the cervical stump. Seventy-one of the patients expressed themselves as being in excellent health; 16 reported that they were in moderately or fairly good health, but felt better than before the operation, and were able to resume their work without discomfort; 6 stated that their health was poor and no better than before the operation. Some patients showed a tendency to obesity, others lost flesh, while the majority exhibited no apparent change. Three patients got married after the operation. Of the 93 cases followed up, 2 had reached the menopause at the time of operation. Excluding these two, menstruation had ceased in 64 cases, and in the remaining 27 there was a periodic sanguineous discharge. The continuation of menstruation was doubtless due to a portion of the corporeal endometrium having been left behind. This seemed to produce a beneficial mental effect, while the cessation of menstruation exercised in some cases a depressing influence. Menopausal symptoms were observed in 52 patients. In 55 cases no difference in sexual appetite was observed by the patient after operation; in 8 it was increased; in 20 it was diminished; in 3 it disappeared; and in 7 it had never been present. A more minute analysis shows that the proportion of cases in which there was no alteration of sexual instincts was more or less the same whether the ovaries were conserved or not, and that while there was no increase or total abrogation of the sexual proclivities among those on whom double oöphorectomy was performed, the number of cases in which there was a diminution of sex instincts was proportionately much larger among those in whom both ovaries were removed than among those in whom one or both ovaries were spared. Examination of the cervix in the 93 cases traced showed nothing abnormal. An important feature disclosed by the examination of these cases was the complete absence of malignancy of the cervical stump. Leucorrhea was noticed in 18 patients, and atrophy of the vagina occurred in some instances.

Gas Cysts of the Abdomen.—Chastenet de Géry gives a brief monographic account of these formations which have been known since 1754, when two cases were mentioned by Combalusier, although these hardly measure up to the requirements of our present knowledge. Nothing further is heard until 1825 when the condition was reported in a pig by Mayer. The first completely authenticated case in mankind was not reported until 1876 by Bang, who found the gas cyst at an autopsy. Other autopsy cases were then recorded and in 1899 Hahn reported the first case in a living human subject. During the past score of years numerous other cases have been reported mostly from autopsies, and the total number is now about 66. Five or six monographic studies have been published without counting two recent Paris theses. The bibliography appended by the authors comprises 66 references. The authors prefer the name intestinal pneumatosis, the condition bearing a close resemblance to hydatidiform mole, being constituted of multiple cystic formations suggesting a bunch of grapes, these varying in size from millet seed to pigeon's egg, while the number may be incalculable. The contents are essentially inodorous gas or gases. The site is the ileum, mesentery, colon, peritoneum—often more than one locality although 18 are mentioned as limited to the ileum; exceptionally they have also been seen in the jejunum, duodenum, appendix, etc. Nearly always the gas cyst lies between the serosa and muscularis and is essentially subserous. Concerning the etiology we are in the dark but there usually coexists some lesion of the digestive tube. Thus in 50 cases analyzed there coexisted 28 cases of pyloric ulcer and much less frequently cancer of the stomach, typhoid fever, intestinal occlusion, appendicitis, etc. There is nothing absolutely known of pathogeny but veterinaries uphold the traumatic theory which makes the condition akin to emphysema. Aerogenic bacteria however have been suspected and apparently isolated by some writers. Diagnosis *in vivo* is seldom made, the symptoms most frequently suggesting tuberculosis of the peritoneum. The percussion sound could readily be confounded with that of meteorism. The presence of an underlying condition like gastric ulcer confuses prognosis while the knife which is often necessary for the latter is hardly indicated for the treatment of the cysts.

Ovarian Autointoxication. — Pamboukis regards the ovary as an eliminative organ through its determination of the menstrual flow. This is but one of its three functions, the others being respectively the genesis of the ovum and the production of an internal secretion of use to the general economy. In ovarian insufficiency these functions may all be compromised and hence after castration they should be in evidence. However, it is quite possible for a partial insufficiency to develop and in the clinic this may be seen in the form of amenorrhea without autotoxic phenomena—for the latter develop when the internal secretion of the organ is in abeyance. In pregnancy we may see amenorrhea plus ovarian autotoxicosis. In the nongravid, absence of internal secretion is expressed by increased adiposity and by the hot flushing and other symptoms so evident in the climacteric. These women menstruate as usual. In another type we see absence of the menses but evidence of an internal secretion. The women are chlorotic and may have epimenstrual bleeding. In a third type we see absence of internal secretion and amenorrhea combined. Of interest is the fact that ovulation goes ahead as usual so that conception is possible. A still higher type exists in which ovulation ceases. It is not quite clear whether the author ascribes the toxemia of pregnancy to ovarian insufficiency beyond the occurrence of the usual symptoms of the climacteric which are more or less in evidence in some women after conception. He does not mention any severe symptoms of pregnancy toxemia in this connection.

Rhinogenic Headache.—Gallusser refers to the difficulty of diagnosticating headaches in office practice. Symptomatic headache, despite the enormous variety, is not so burdensome because with time we can find the basic condition, but the essential or primary headache must necessarily be difficult to diagnosticate. These headaches must ultimately be shown to be symptomatic of some other ailment. When eyestrain was recognized as a cause of "essential" headache a great step was taken in advance and the author believes that he has relegated another form of socalled primary headache to a secondary source, to wit, frontal sinus empyema. It goes without saying that the author does not refer to manifest nasal lesions, for the preliminary examination of these patients shows healthy nasal chambers without deviated septum or spurs. Hence in routine work it would be overlooked that the frontal sinus for example was the seat of an empyema. In a case cited the headache was so severe that patient made an attempt at suicide. Something had to be done in so desperate a case, and the author who had become suspicious as to the possibility of a frontal sinus empyema used a trephine with happy results. He would in these unmotivated headaches attended by intense suffering trephine these sinuses purely as an exploratory puncture. If he struck pus he would keep on and do a radical operation. The trial operation is done intranasally, and of course the operator must be a rhinologist.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held December 18, 1919.

THE PRESIDENT, DR. GEORGE DAVID STEWART, IN THE CHAIR.

The Dispensary Situation in New York City.—A Report on a Year's Investigation and Study by the Public Health Committee.—E. H. LEWINSKI-CORWIN, Ph.D., submitted this report. (See p. 180.)

Dr. S. S. GOLDWATER said that he supposed the Public Health Committee might be regarded as the representative of the city; at any rate the dispensaries had welcomed its investigation. He could not help thinking that there was a very striking and delightful contrast between the dispensaries in their being willing to wash their dirty linen in public, so to speak, and the behavior of a portion of the medical profession. Some of the members of the latter, when it was suggested at a recent conference on health insurance that the medical service rendered the poor was not what it should be, urged that nothing of that sort be admitted, because the medical profession already stood too poorly, and if they confessed that their work was not up to the standard it would stand still lower in the public estimation. The medical administrators of dispensaries were frank in confessing that they had not accomplished what they should have done. Dr. Lewinski-Corwin's report might lead one to feel rather discouraged, but if they recalled all the improvements which had taken place during the past twenty years they would be able to record considerable progress. In fact, the report showed progress in a number of lines, and particularly in regard to the employment of social workers and follow-up work. The report insisted that a dispensary should have a definite and unequivocal policy and that it should be entrusted to a competent executive for enforcement. What should be the definite policy of a dispensary? In connection with this question the other questions were what were the dispensaries trying to do, whom did they expect to serve, and what financial support was required? A striking feature of the report which the brief summary to which they had listened did not bring out sufficiently was that a large proportion of those who went to dispensaries were not the very poor, but those who were able to pay their way and ordinarily did pay their way. This suggested that it might be advisable to make two classifications, one of which should be a pay dispensary, and the other a free dispensary. If this division were made it would relieve many who came to a dispensary much against their will, and who did not wish to be objects of charity and who ought to be relieved of the feeling that they were dependent upon public charity. There were those who claimed that all clinics should be diagnostic clinics. Nevertheless, it would have to be conceded that 50 per cent. of the patients who came to the dispensaries did not need a thorough physical examination with all the elaborate machinery of a full-fledged diagnostic clinic. It was fortunate that this was so, for if such a complete examination were necessary in every case the cost would be on the average four or five dollars per patient. If these two classes of cases were recognized the simple cases that did not require complete physical examination and the more complicated cases that did require such thorough examination, the organization of the dispensary could be modified to meet these requirements. It would be necessary to regulate the administrative machinery so that each patient would be placed in the class to which he belonged. This would mean a competent registration clerk. He had in his mind a clear idea of how this could be carried out. It took courage to even mention health insurance in an audience of physicians, but he felt that health insurance had a very vital relationship to the dispensary problem. Under a well-planned scheme of health insurance the patient with a trivial ailment would be cared for in his home by the district practitioner, and the dispensary might become a clinical center for everybody able to pay his or her way. As a matter of fact the dispensaries were being used somewhat in this way now, for many patients came with a slip of paper from their family physicians calling upon the dispensary to perform some special work for which they were equipped and which the private practitioner was not so well prepared to do. He had been quite thoroughly convinced that the suggestion of the report urging a satisfactory correlation between hospitals and dispensaries was imperative in order that the dispensaries might have the benefit of the services of the best diagnosticians in the city. If the dispensary was an integral part of the hospital service both physicians and the people would turn to it. While some were loath to acknowledge the fact, others freely admitted that the medical service given to a large mass of the people was inadequate, and the question was how to remedy the situation. His idea was that the hospital and dispensary should be correlated, and that there should be a medical executive in control. The staff should be graded so that the new man should enter the lowest grade in the dispensary and, after serving a probationary period, become a member of the staff. As he progressed he might work his way up through the various grades of the dispensary and then be admitted to the hospital staff. Under present conditions it was not the doctor who was on probation, but the dispensary, and as a rule it did not come up to the mark and the doctor did not remain long. The dispensary should be a post-graduate school of instruction. The investigation had shown that as a rule the special dispensaries were better than the special departments of general dispensaries. The special dispensaries had, he thought, been started in most instances, because the general dispensary had not made adequate provision for them. He thought the special dispensary should be correlated to the general dispensary, as in this way it would offer advantages to both the medical men and the people who came to it for treatment. The dispensary was a potential health center and some dispensaries at the present time were engaged in public health education and were equipped with every sort of educational contrivance that was of aid in this work. To those who were advocating a department of preventive medicine in connection with dispensaries this was a happy sign. The report did not sufficiently emphasize the educational value of the dispensary to the physician and to the community at large. A very striking development in connection with the dispensary was the social service department. He knew of one instance in which a social service department had developed to such an extent that it had asked that a physician be attached to it. If this request were granted he supposed the physician would soon want a social service department for his work and this process might continue indefinitely. While recognizing the importance of the social service work, he did not think such a department should be expanded indefinitely. The suggestion had been made that the social service worker should not undertake the duties of a nurse, but if nursing services were required should refer the work to the district nursing organization. Surely since nine-tenths of the social workers were trained in nursing he felt that this would be an unnecessary duplication of effort. The inauguration of follow-up work had been a step in the progress of the dispensary, and it had shown that there were often good reasons why people did not come back to the dispensary to continue treatment, and usually the reasons were not to the credit of the dispensary. In discussing the question of making appointments for patients to obviate the necessity for long waits, Dr. Goldwater said they had a system at the Mayo clinic under which they made appointments, but nevertheless the patients frequently had to wait a long time. A dispensary in England conducted a lunch counter so that patients would not starve to death while waiting. He did not see how the waiting could be avoided, so long as there were a great many patients who persisted in coming a couple of hours before the time set for their visit. Districting the city had been suggested, but this they were not likely to have so long as the Board of Charities continued in its *laissez faire* attitude. They might, however, have a volunteer association of dispensaries which would bring about a districting of the city without compulsion, but he felt that the most hopeful suggestion from the standpoint of preventing overcrowding was that under a well worked out system

of health insurance many of the patients who now went to the dispensaries would be cared for in a doctor's office. The clinics should then be improved and become diagnostic centers where doctors could send patients for special reasons. More could be done in the making over of the dispensaries by continuous than by intermittent effort. The first essential was a fit place in which to do the work so that the dispensary could render the public the service it was its duty to give.

Dr. WALTER I. NILES stated that it was obvious that a successful dispensary depended upon a competent, enthusiastic, well-informed physician attached to it. As a rule a physician attached himself to a dispensary more for the opportunities it offered for instruction than for anything else, and an important question was how these facilities might be increased. It seemed to him that the best way was to have a number of consultants who should visit the dispensary occasionally as consultants in special cases. In a dispensary where the group system was carried out the consultant would not have to come oftener than once in two or three weeks, or once a month to a particular group. The educational facilities of the dispensary should be cultivated to a greater degree for both graduate and undergraduate students. It might be said that in general we knew more about the results of disease than about its beginnings; it was in the dispensary that one saw and could study the beginnings of disease. In connection with the study of the beginnings of disease there should be a study of the surroundings of the patient, both in his home and in the industry in which he was engaged, so that they might learn more of the conditions that conduced to disease. At the present time the graduate students were going into the hospitals more than into the dispensaries. In order to change this it was only necessary to organize groups in the dispensaries that would provide good teaching material, then the students would come back. There was a very good demand for such groups, yet their number was less than formerly. In the plans of the newly organized Association for Medical Education, which was aiming to develop New York as a medical center, the possibilities of the dispensary should be taken into consideration, especially in reference to those dispensaries correlated with hospitals connected with teaching institutions. In order to economize the time of physicians there should be a greater employment of clinical helpers and volunteers. Many of these women were perfectly competent to do many things which formerly were done by the doctors, and they could be trained to do many more things. It was perfectly possible for a trained secretary to take the clinical part of all histories. In addition to clerical duties, such assistants often brought into the dispensary a critical spirit which tended to elevate the character of the work done in the dispensary. An effort should be made to think of more ways of minimizing the drudgery of dispensary for the doctor and of giving the greatest opportunities for instruction. Another point considered in the report was the advantage of limiting the number of patients admitted. It was obvious that no more patients should be admitted than could be cared for properly. It would take only a little development to attract a larger number of competent men to the dispensaries than they were now getting.

Dr. JOHN A. HARTWELL asserted that this report was for the purpose of emphasizing by the presentation of actual facts the trouble known to those associated with the dispensaries, namely, the finding that the dispensary system in New York had broken down. Dr. Lewinski-Corwin had not emphasized that fact as the full report did. The summary they had listened to gave no idea that the situation was as bad as it actually was. Good suggestions were offered, but the question was how they were to be put into effect, and why some of these things had not been done before. In order to arrive at an answer to these questions the question came up as to how the dispensaries had arrived at the state they were in. He did not agree with Dr. Goldwater that the dispensaries had made any such marked progress as he had indicated during the past twenty years. The reason the dispensary situation was serious was because of the general change in hospital administration. Twenty years ago a physician took care of a hospital himself, and he did not want anyone else to help. There was little laboratory work at that time, and the result was that the young man had little to do in the hospital and turned to the dispensary to get his education and opportunities. The young men worked hard to get into the dispensaries, and it was not uncommon to have long waiting lists. Now the opportunities for in-service had increased and consequently the young doctors dropped into hospital work, and the dispensaries were gradually more and more neglected until it had finally come about that the doctors put the dispensary on trial, as Dr. Goldwater had said. Who had neglected the out-patient department, and why? It had been neglected because other work had become more and more important, and consequently the dispensary was cut adrift. It had been only recently, within three or four years, that the situation was recognized, and the cure in some instances had been reached. Where this had been done it had been brought about by some one man of ability, energy, and perception who took up the work and through whom the problem was solved. He thought the answer to the entire problem was that boards of trustees of hospitals should definitely recognize that their dispensaries were not anywhere near on a par with the in-service in most of the hospitals, and the next thing was a demand that the dispensaries be raised to a better standard. A dispensary should take the attitude that it would treat only as many patients as it could care for properly without overcrowding. Each institution should study the situation as it was, and work out its own problem as it existed in that institution. A solution had been arrived at in several dispensaries. In some dispensaries the facilities were very poor as regarded architecture, and there was also the question of the difficulty of obtaining aid in the keeping of records in both hospitals and dispensaries. The records of the dispensary should form a part of those of the hospital. Whenever a dispensary had been run successfully one man, or possibly two, had been responsible for it. In closing, Dr. Hartwell said that if his criticism of the dispensaries seemed severe he wished it understood that what he said applied to himself as well as to others, for he, too, had neglected the dispensary. At Bellevue, he said, the conditions in the dispensary were desperate. The dispensary there was built when the demands made upon it were only about one one-hundredth of what they were to-day. The children's and tuberculosis dispensaries, however, could not be beaten.

Dr. CHARLES E. NAMMACK said his only justification for accepting the invitation to discuss this complete, comprehensive, and painstaking report was on the basis of his experience. He therefore apologized for the introduction of his personal experience. He agreed with Dr. Hartwell that conditions at the present time were deplorable. They had a dispensary law, but it was a dead letter. A law to be effective must be founded on the customs and sanctions of the people, and any law that did not have this foundation became a dead letter. For this reason the latest constitutional amendment he believed would not be enforced. As to the dispensaries, one and one-half million, or 20 per cent., of the population of New York availed themselves of the medical service the dispensaries offered. It necessarily followed that there was a great abuse of the dispensary. He did not agree with the report that the abuse of the dispensary service was limited to 2 per cent. of the population, nor did he agree with the report of the investigation made by the Medical Society of the County of New York, in 1912, that the abuse was limited to 10 per cent. of those treated in dispensaries. In the early years of his professional life he had employed his spare time in making an investigation of this question, using the best methods he could think of. Much of the statistical evidence that had been accepted for these reports was based upon the statements made by the patients themselves as to their ability to pay. It had been his experience of human nature that an unworthy person would be sufficiently unworthy to tell an untruth in reference to his ability to pay a doctor's fee. Hence, in making his investigation he had based his judgment of the patient's ability to pay upon the style in which he lived and

the amount of rent he was paying. Judged by this standard he found that 23 per cent. of the people accepting free treatment at dispensaries were able to pay a moderate fee to a physician. Forty years ago people were somewhat more justified in going to a dispensary than they were to-day, because adequate medical advice was not as easily obtainable then as now. In commenting upon conditions at that time, Dr. Abraham Jacobi said that all that was necessary to secure success in the medical profession was a carriage, a diploma, and plenty of assurance; conditions were entirely changed to-day, when there was not a square block in the city where one could not find one or more capable doctors willing to give advice for a moderate fee. Coming to the question of dispensary administration, a dispensary should have at its head a man of many parts; he should be a competent physician, a capable executive, and should know human nature. For the services of such a man the dispensary was willing to pay $1,200 a year. Of course, it was impossible to keep a man of that type on such a meager salary to-day. With reference to the question of the dispensary charging fees, he felt that when they began to talk of charging fees they were losing sight of the primary function of the dispensary, which was for the treatment of the poor, and medical service should be as free as anything else was to the poor. The laborer who could pay a dispensary fifty cents for a visit should be sent to some physician, and that fee would answer for the specialist, too, where the patient could pay no more. He had sent many a patient who was unable to pay a specialist's fee to a specialist with an explanation of the circumstances, and he had never known such a patient to be refused treatment, and often the specialist had refused to take any fee whatsoever, even though he might have spent hours on an obscure case. As to the question of diagnostic clinics, that question had been discussed at Bellevue and the conclusion reached was that a diagnostic clinic would take too much time and would distract attention from the patients who urgently required treatment. When a case was so obscure that it required the service of a number of consultants and a number of special examinations, it was not a case for the dispensary. A qualified man in a dispensary should be able to make a fairly accurate diagnosis in most cases without the complicated machinery of a diagnostic clinic. A health center in connection with a dispensary might well be established, but its activities should be conducted in the evening when working people could take advantage of the facilities it offered. Another point was with reference to the pay of the staff. He felt that the laborer was worthy of his hire, and that every dispensary physician should have a small salary (the wages of a plumber would do). Many young men were willing to give their services for a dollar an hour. In Bellevue the doctors in the tuberculosis dispensary were paid by the city. By paying a small salary the dispensaries would attract men not attached to hospitals. As to appointments, they should be made as suggested in the report, and the men could be promoted as they showed progress. The keeping of records was a problem not only in dispensaries but in hospitals. They had taken young women at Bellevue and trained them as filers and indexers, and when they were trained they commanded so much larger salaries in business houses that they could not keep them in the hospital. Such labor was not available to the dispensary at present. It was regrettable that when so many large gifts were being made by philanthropists that no one had thought of endowing clinics, so that doctors, clinical secretaries, and social workers could be paid and the poor properly cared for. He felt that the follow-up system was the hope of the future. It was the one thing that was going to raise the standard of living. The one great advance that had been made by the dispensaries was the establishment of social service departments. By this means they reached the people; and even though their appeal could not break through the ignorance, vice, sloth, and religious prejudice of the older people, the children could be reached. As regards districting the city, he was very much in favor of that, but the suggestion had been made before and had met with opposition because some institutions wanted to draw their clientèle from all over the city and from other localities as well. They said their contributors would not agree to the limitations that would be imposed by a districting plan. The districting of the city would probably never be brought about, though such a plan had great advantages, as demonstrated by the tuberculosis clinics maintained by the city. His idea briefly was: (1) To abolish all fee charges. (2) Pay every member of the staff. (3) Increase equipment. (4) Expand service. (5) District the city.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting Held November 25, 1919.

DR. SOLOMON WIENER IN THE CHAIR.

Carcinoma of the Vulva. No Recurrence for Three Years.—Dr. THOMAS H. CHERRY presented this patient, a woman, 71 years of age, unmarried, and a virgin. Her previous history was negative except for pneumonia twenty years ago. The menopause occurred at the age of 38 years. Two weeks before she came under his observation she began to notice a swollen and tender area upon her external genitals. This began to increase in size and became very painful to the touch. On voiding there was considerable irritation and burning. There was no leucorrheal discharge. Physical examination showed a red growth situated on the left labium majus near the clitoris, similar in character to exuberant granulation tissue. This had a conical base and was raised from the skin about three-quarters of an inch. The left vulva was slightly edematous. On the external aspect of the left labium majus a slight superficial excoriation was present. The growth was exquisitely tender. No inguinal glands were palpable. A diagnosis of epithelioma of the vulva was made and operation advised. A month later the patient was seen again when the growth appeared to be about the same, but upon the opposite labium majus there was a small superficial ulcerated area with indurated base. The operation was delayed somewhat as the patient's blood pressure was 190 mm. systolic. After rest in bed for a week the blood pressure was reduced to 160 mm. Operation was then performed under chloroform ether anesthesia, the typical operation as described in Crossen's Operative Gynecology being employed. The incision was made in the left inguinal region and extended across the abdomen and over the pubis, well above the mons veneris, to the inguinal region of the left side. At the outer extremities of this incision another incision was made curving downward and inward, completely encircling the vulva. An additional incision was made around the external meatus of the urethra, encircling it for three-quarters of the way. This was extended down laterally to the vestibule, meeting the first incision. These incisions were deepened so that the entire vulva, Bartholin glands, vestibule, clitoris and mons veneris were freed from the underlying structures. This block of tissue, including the lymphatic vessels that drained into the groin, were dissected upward to each inguinal origin, and the vessels exposed in such a manner that the macroscopic glands were removed *en masse*. All the bleeding areas were clamped and ligated, the edges of the wound were approximated by interrupted silk worm gut sutures; continuous catgut sutures were placed in the skin after placing superficial relaxing incisions on the thighs to allow the wound to close without tension. Drains were placed in the center of the wound and in each groin. The patient left the operating table in good condition after two hours and ten minutes, and was discharged from the hospital on the thirty-fifth day following the operation. On examining this patient six weeks later a complete prolapse of the uterus was found. Since that time she had been treated at the General Memorial Hospital by *x*-rays with the hope of preventing the formation of metastases and recurrences. The pathological examination of the tissues showed typical epithelioma. Section made of the inguinal glands showed no metastatic growth.

The Therapeutic Value of Radium.—Dr. G. S. WILLIS read this paper in which he said that exposure of the tissues, normal and abnormal, to the rays of radium caused certain cell changes, the results of which were shown by the swelling of the whole cell, enlargement

of the nucleus, and later the cell became a colloidal mass capable of being absorbed into the general circulation. Upon our ability to bring about this change depended the therapeutic value of radium. The value of radium treatment depended upon the accessibility of the growth and the physical condition of the patient who must withstand the constitutional effects of the action of radium. The prognosis and the therapeutic value of radium depended upon the ability of the patient to eliminate the toxemia which presented to a greater or lesser degree in all cases under radium treatment. As to the cause of this toxemia, he did not know whether it was the introduction into the general circulation of these disintegrated cells, or whether it was the result of some unknown effect of radium. The symptoms of this toxemia were prostration which might continue for a week or more, a marked diminution in blood pressure, a rise in temerature, and not infrequently nausea and vomiting—in fact a general asthenia might develop which it was impossible to combat. He had seen certain cases under treatment, and although the growth might have disintegrated to a marked degree, the general condition of the patient became hopeless. The major gynecological conditions in which radium therapy was indicated were malignancies, hemorrhage, and fibroma. In the treatment of malignancies radium occupied a similar position in therapy to that of salvarsan in the treatment of syphilis. Like salvarsan, it rarely alone cured, and, like salvarsan, it was necessary in the treatment of all malignancies. It was indicated in two classes of cases, in the operable as a pre-operative measure, and in the inoperable in which one might expect to cure at least one or more of the three cardinal symptoms—pain, hemorrhage, and fetid discharge. As a preoperative measure, he believed all cases should be treated with radium before surgical means were instituted. If this were done one might expect that metastases would not take place. In the inoperable conditions the success of radium treatment would depend upon our ability to combat the resultant radium toxemia. The suitability of an inoperable case for radium treatment was ascertained by making a general physical examination and by determining the functionating ability of the kidney. If the specific gravity was low and casts and albumen were present, a chemical blood examination was made to determine the already present retention products, and a phthalein test was made. Lastly, a complete blood examination was made. The contraindications to the use of radium would be in the presence of a growth which was inaccessible to the action of the rays of radium, and evidence of a kidney whose functioning power was less than 50 per cent. In this class of cases very little benefit was to be expected from the use of radium. As to the dosage in malignancies, it was his experience that not more than 50 milligrams should be used at a time, and the treatments should be as prolonged as possible. If it was possible to cross fire with a tube of 100 or 200 milligrams applied to the abdomen the results would be better. Daily blood counts should be taken and the frequency of the treatment should depend entirely upon these. In the treatment of hemorrhagic conditions a tube of radium of 25 to 50 milligrams inserted into the uterus for five or ten hours, according to the severity of the symptoms, would control most of the bleeding. This application was attended with but little danger, and in the opinion of the speaker was indicated in any and all such conditions. In the treatment of fibroma with radium each case must be considered from the individual standpoint. If hemorrhage was present radium should be used at once, and after a sufficient length of time the growth might have diminished in size sufficiently to make surgical interference possible.

Roentgen Therapy in Gynecology.—Dr. W. H. MEYER read this paper in which he said that through the agency of roentgen rays stimulation, inhibition, or destruction were applicable at will to certain living tissues. However, because of marked differences in radio sensibility of various cellular structures, three effects might occur in the same exposed area. Since the vulva, vagina and cervix might be classed as superficial structures, in so far that the direct application of the rays was a possibility, a classification need be no different than that of diseases of the skin and the tangible mucous membranes in other parts of the body. Superficial lesions naturally fell into three groups: (1) Those to be benefited by stimulation; (2) those in which an inhibitory action was desired, and (3) those conditions in which total destruction was the aim. Since employing the absorption rate as a basis for their dose measurement they had passed their fiftieth consecutive case of superficial malignancy with satisfactory results. Some of these cases were now in their third year following the first treatment and to all appearances remained perfectly well. Differences in penetration and filtration were employed to suit the individual case; the estimated absorption, however, was the dose factor in each instance, and the result had been uniform whether the lesion was purely cutaneous or at the muco-cutaneous junction, whether prickle cell or squamous cell in type. They were now producing this result at a single sitting, the full treatment to a single area not requiring more than fifteen minutes. With careful blocking for the protection of normal structures, a somewhat less severe application would suffice for most superficial benign growths; berrucæ, moles, and superficial nævæ fell into this group. With those malignant conditions involving up to the first centimeter in depth, where a total absorption could be brought to bear, similar good results were to be expected. However, with those lesions situated below the second or third centimeter in depth and in inaccessible regions, the difficulty of satisfactory treatment became greater and speedily diminished with increasing depth. In malignancy, superficial or deep, the desired results would have to be obtained under the following conditions: 1. Destruction of the malignant cells; (b) inhibition to neighboring healthy tissue; (c) stimulation to the surrounding healthy tissue. With more or less superficial tissues this combination was obtainable. In deep-seated and more widespread malignancy, usually the best one could hope for was an inhibitory action on the malignant cells and stimulation of the surrounding normal tissue. This was the minimum dose that one should attempt to administer. The least desirable reaction, one which still had its advocates, was dependent, according to one's theory, upon (*a*) stimulative dosage to the normal metabolic processes (by direct high transmission rate); (*b*) electronic disturbance and rearrangement (by secondary ray effects); (*c*) the formation of enzymes or antibodies (indirect radiation). This was the status of the treatment by radiant energy as it appeared to-day. The writer's comment here was "Know that your radiologist knows his roentgen rays and prohibit the promiscuous use of this agent by unskilled and untrained incompetents. On the other hand, strict co-operation should exist between the surgeon and the radiologist for both pre-and post-operative radiation." In discussing the treatment of uterine hemorrhage, menorrhagia, metrorrhagia, symptoms of the menopause, and uterine fibroids, the writer said that in a single treatment of from forty to ninety minutes' duration, depending upon the type of the patient, a permanent cessation of the menstrual function and of hemorrhages could be produced. In their last series of 20 consecutive cases in which dosage based on absorption percentage administered at a single sitting was employed, the ages ranging from seventeen to forty-five years of age, they had not a single failure. The symptoms of the menopause was materially diminished and the period of suffering shortened by one or two applications. When more than one treatment was to be given, from four to six weeks should elapse between applications. The fibroids best suited to radiation were the intramural type. The subperitoneal, and particularly the pedunculated, variety had best be operatively removed. The sunmucous or polypoid variety of fibroids were practically contraindications to the use of radiography. The writer had based his dosage measurement on the rather materialistic assumption that work done required the expenditure of energy which must be transformed or consumed at the proper site to produce results. As to the logic of dosimetry by the estimation of absorption, attention was directed to the following points: (1) The amount and pressure of current energizing the roentgen tube could be metered; (2) the quality and quantity of *x*-ray generated were measurable; (3) various methods of surface dosimetry had been devised. The

more penetrative the rays and the greater the filtration, the less the possibility of reaction with the same full measured incident dose. This might be explained on the basis that high penetration with strong filtration meant a high transmission rate, and since the difference between the incident dose and the transmitted dose in any given area might be assumed to indicate the absorption rate, this absorption must of necessity be low under the conditions of high penetration and strong filtration.

Dr. WILLIAM P. HEALY said he was not familiar with roentgen therapeutics but they had used radium in cases of menorrhagia during the child-bearing period and in cases of metrorrhagia not associated with any neoplasm or change in the size or form of the uterus but in which the patient was bleeding profusely. In young women under thirty years of age with this symptom he had used 25 mgs. for a limited number of hours, eight at the most, and none had as yet become pregnant, though the periods had been adjusted to four or five days, and the question was whether the Graafian follicles had been damaged. He asked Dr. Willis if he had followed cases long enough to know whether pregnancy occurred, whether the children born were normal, and whether pregnancy occurred as frequently as in women not thus treated.

Dr. LEROY BROUN, in speaking of fibroids and the use of radium, expressed the belief that radium unquestionably had a field, and under certain conditions a field in the treatment of fibroids, but he said this advisedly. In their study of fibroids at the Woman's Hospital the operative death rate was 1.5 to 1.8 per cent. This was based on almost 2,000 consecutive operations, including the difficult and simpler ones, together with those who were poor surgical risks. They could not ask for better than this. One might have tubo-ovarian conditions which might need operation of themselves and which in the presence of large fibroids could not be diagnosed. These constituted about 10 per cent. of all cases and radium or the *x*-ray would not be used in the treatment of such cases. Fibroids underwent necrotic changes which in the majority of cases were not diagnosed before operation and which would contraindicate the use of radium. Ninety out of 1760 consecutive cases, or five per cent., had this necrotic condition. Carcinoma of the body of the uterus, a condition at times discovered and at other times not, existed in 15 per cent. of cases. For such a condition, while radium miyht be used it was by no means the best treatment, since complete removal gave such excellent results. Added to all this there was the uncertainty of making a clear differentiation between an edematous fibroid and a tense ovarian cyst. Errors of this character had been made and would continue to be made. One would certainly not intentionally use radium or *x*-ray for ovarian cysts. Radium had a field, however, in young women with clearly defined and uncomplicated myomatous uteri that were giving symptoms. In such cases he would prefer to use radium to save the patients from the complete removal of the uterus. If such a fibroid, however, could be removed by myomectomy this was a different matter and he would choose the operative course. These cases, however, were generally those of diffuse adenomyoma and not of removable fibroids. The general practitioner saw laudatory reports of the treatment of fibroids by radium and *x*-ray and was anxious to give his patient the benefit of this new treatment and to avoid operation if possible. He had not been trained to recognize and possibly had not been informed of the coincident existence of pathological conditions. He sent his patient to the *x*-ray specialist who was less trained to recognize such complications and who treated the patient on the diagnosis of the family physician. He thought that in not always being able to map out clearly the abdominal condition before the abdomen was opened was where the error was made in advocating under such conditions a line of treatment (*x*-ray or radium) which was untenable in certain conditions.

Dr. GEORGE GRAY WARD said that at the Woman's Hospital they had been using radium quite extensively during the past years and he could add his testimony to its great value as a palliative measure in inoperable carcinoma of the uterus. They had also had satisfactory results in the treatment of menorrhagia without demonstrable pathological changes of the uterus by means of radium. He was entirely in accord with the remarks of Dr. Broun, namely, that a careful diagnosis was needed before *x*-ray or radium could be advised. There were many cases in which the use of the *x*-ray was inadvisable. He cited an instance of a woman who was treated for a fibroid by the *x*-ray and had suffered ever since with marked pelvic pain; several men who saw her thought the pain was due to the *x*-ray treatment. In that case they had used radium and there had been no hemorrhage since the application was made, but it was too soon to say that the condition had been cured. Where one found involvement of the adnexa, pedunculated growths and adhesions of the intestines, such patients were not suitable for radium treatment and should be operated upon. In other words, a careful diagnosis was essential, whether one used *x*-rays, radium, or operated.

Dr. JOSEPH BRETTAUER said he had not heard the papers and so his discussion would not be on the paper but would be germane to the remarks of the speakers who had discussed the papers. As far as treatment of fibroids of the uterus with *x*-rays was concerned, he had learned to carefully select his cases for this specific form of treatment. The more experience he gained, the better and more satisfactory his results were. This was mainly the reason he had never resorted to radium for the treatment of fibroids. He recently had occasion to remove a rather large fibroid where radium had been used. All the symptoms complained of previous to its use had grown rapidly worse, and removal was necessary one year after its application. Radium as a palliative measure in the treatment of advanced cases of carcinoma of the cervix was a valuable addition to their therapy. The results were marvellous at times. The application of a small amount (60 milligrams) for from twelve to eighteen hours was followed by the disappearance of hemorrhage, foul discharge, and excruciating pain, and the general condition improved in a remarkably short time. Of course there were, as a rule, metastatic foci in some other organ to which the patient eventually succumbed.

Dr. HAROLD BAILEY said he knew of one case (mentioned by Dr. Williamson) in which pregnancy followed after radium had been used. He had never treated any woman with radium who after the treatment became pregnant. He had treated only one young woman for bleeding. He agreed with Dr. Brettauer in regard to the palliative effects of radium for uterine carcinoma. He uttered a word of warning, however, namely, that part of the cancer within one or two centimeters of the point at which the application was made might be caused to disappear and there might be entire local healing and yet the cancer was still growing and would eventually kill the patient. Local healing within a year did not mean that the patient was cured. Dr. Bailey said he had seen patients shown as cured and in whom there was absolutely no growth by sight or touch, and still they were not cured as later developments proved.

Dr. JAMES T. CORSCADEN said he had treated some 200 cases of metrorrhagia and fibroids and about 40 cases of epithelioma. In epithelioma it must be remembered that the disappearance of the superficial growth gave no indications of the metastases or extensions into the broad ligaments. One could easily fall into error in attempting to remove such a uterus. He thought no better indications had been laid down than those of Dr. Clark of Philadelphia, who divided his cases into clearly operable, inoperable, and doubtful. The two latter were treated with radium. Time enough had not elapsed for them to tell whether a delay of three or more weeks was deterimental to the patient or whether 800 or 900 milligram hours had any destructive effect on the cancer cells distant from the uterus. He thought it would be safe for the majority of them to either operate or use radium in full destructive doses. In regard to metrorrhagia in the grossly normal uterus and in fibromyoma, he felt that we had a much wider and more useful field for radium and the *x*-ray. However, before applying radium to what appeared to be a pathological uterus, one must consider the effect of these agents on the normal animal. They saw then that next to the lymphocyte and spermatozon the

Graafian follicle was the most susceptible to the *x*-ray and radium, while the blood vessels and smooth muscles were affected only by much larger doses, so that when one treated a fibroid with *x*-ray or radium in order to get any direct action on the muscle he must give a dosage many times as large as that necessary to destroy a Graafian follicle. In the young woman who wished to bear children the *x*-ray and radium should be used with the greatest caution. Dr. Brettauer laid his finger on the key to the situation when he emphasized the necessity of careful selection of cases. It was important that greater diagnostic effort be employed in the future than in the past. It was his experience that fibroids had very few symptoms except bleeding, a sense of weight in the pelvis, and frequent micturition. When other symtoms occurred it was important to rule out pathological condition of the tubes, ovaries, and appendix. One case, a tuberculous kidney, required four cystoscopies before a diagnosis could be made. On the other hand, one could not operate on these various diseases merely because of a coincident fibroid. They should be handled according to their individual indications.

Dr. WILLIAM H. MEYER said the one phenomenal thing in this discussion was the rather confusing impression of the effect of radiation, namely, that in one case the *x*-ray was found to relieve pain and that in the next case the patient was made worse by the treatment; in another case amenorrhea was produced while in the next hemorrhage grew worse. Assuming a correct diagnosis he did not believe they would find this difference in result if the correct number of areas were employed and the proper dosage applied. Mention was made by one of the speakers of conserving the menstrual function. In women over forty it did not make much difference whether they continued to menstruate a few years longer or not and besides the symptoms of the menopause were materially lessened (from a point of time at least) when roentgen therapy was properly applied.

Dr. WILLIS, in closing, emphasized the necessity of standardization as regards radium. He said we knew that radium had a place therapeutically, but he did not think it had been established just what place. There was no question but that radium would control hemorrhage and that it was a good treatment applied to certain growths before operation. The whole question depended upon the accessibility of the rays of radium to the growth one is endeavoring to affect. The Mayos spoke of this process as "sickening the cell" and operated within three weeks after the application of radium. They gave a certain dosage which was comparatively small, and within three weeks they operated with excellent results. During the past two months he had treated two cases of carcinoma of the uterus with radium and hysterectomy and in each case without the slightest trouble. These cases were at the present time in good condition, but it was too soon to say what the final result would be.

Dr. WARD asked if he treated those cases with radium postoperatively.

Dr. WILLIS replied one they did and the other they did not because they did not think it necessary. If there was an ulcerative nodule they used the radium postoperatively, but not on general principles.

Dr. BRETTAUER said that in a few borderline cases he had used 40 milligrams of radium for twelve hours before operation. At the time of operation it was noticed that the peritoneum of the pelvis could not be stripped off bluntly anywhere. It was closely attached to the underlying tissues, preperitoneal fat was absent, and isolation of the ureters could only be accomplished by the use of a sharp instrument, never by the finger alone. He asked Dr. Willis whether such observations had been made by him.

Dr. WILLIS replied that the adhesion of the peritoneum was probably due to overradiation and he thought that accounted for what was found in those cases. It was impossible in radium therapy to treat the exact situation that one wished to treat and to limit the action of the radium to that region.

Dr. BROUN asked Dr. Willis if it was not his experience that after the use of radium operation was made more difficult as Dr. Brettauer had brought out.

Dr. WILLIS said that had been their experience and that was why the Mayos operated within three weeks after the application of radium. Their idea was to "sicken the cell" by the use of radium so as to prevent metastases. If one waited more than a few weeks after the application of radium operation was made more difficult.

Dr. HAROLD BAILEY verified what Dr. Brettauer said with reference to the increased difficulty of operation following the employment of large doses of radium. They had used large doses of radium in the treatment of cancer and four weeks afterward the difficulties referred to were present.

A Roentgenographic Study of Abdominal Organs After Intraperitoneal Inflation with Oxygen. — Dr. ARTHUR STEIN and Dr. WILLIAM H. STEWART made this presentation. (See Report of Medical Society of the County of New York, MEDICAL RECORD, Oct. 27, 1919.)

Dr. ALFRED MEYER said he had come, though not a member of this Section, because he was interested in this subject, and had had an extensive practice in artificial pneumothorax and a limited one in pneumopericardium. He had stated before the American Medical Association, in 1917, that it was his belief that there was a greater field than had been supposed for the introduction of gas into the various serous cavities of the body, both for diagnostic and therapeutic purposes, and he strongly urged that such injections be made into the abdominal cavity after the aspiration of ascitic fluid due to a variety of causes. He stated that though this had not been of value in a few cases of cirrhosis of the liver at Mount Sinai Hospital the work should be repeated on a larger scale. He felt that if medical men kept on studying along this line they might steal a march on the surgeons and cure some cases of tuberculous peritonitis by the injection of atmospheric air or of oxygen. He saw a great deal of pulmonary tuberculosis, but he had not seen a case since then that had justified the treatment, although he had seen cases of hemorrhagic pericardial effusion of obscure origin in which he repeatedly made a pneumopericardium—the first on record in the United States. But he was delighted at the value established for these injections from the diagnostic point of view by Dr. Stein and Dr. Stewart. He would like to ask, however, if these patients who had had oxygen injections into the abdominal cavity complained of pain, why should not nitrogen be substituted for oxygen, and if nitrogen were not available why should not air that had been filtered through cotton to sterilize it be used? It might be that the injection of atmospheric air would eliminate the pain because it was more bland, though open to the objection possibly that it was absorbed more slowly than oxygen. They had spoken of using large amounts of oxygen; he could see a close analogy between the use of large amounts of oxygen in the abdominal cavity and the use of large amounts of nitrogen in the thoracic cavity. Just as large amounts of nitrogen with high positive intrapleural pressure might cause rupture of a pulmonary cavity situated near the surface with consequent infection of the pleura and the death of the patient, so, too, large amounts of oxygen injected into the abdominal cavity might lead to similar accidents through the rupture of adhesions. These fifty-one cases had run along without disaster thus far, but it was a very wise precaution to reduce the total quantity injected.

Dr. ARTHUR STEIN said it would, of course, be quite possible to substitute air for oxygen in the application of this method. The sterility of the air, however, was of no particular importance. Whenever a laparotomy was done air which was not sterile entered the abdominal cavity and with no untoward effects. Oxygen possessed the advantage of more ready absorption, the rate of absorption varying from case to case. In some instances absorption had proceeded so rapidly that at the end of an hour and a half they could not take the picture; in other cases it took from twenty-four to forty-eight hours. They were not using a large quantity of oxygen; in most cases about 2 liters. The point was that they individualized. They recommended careful observation of the patient during inflation with palpation of the abdomen, etc., and when pain was elicited by the pressure from the gas it was time to discontinue the injection. As a rule, however, the patient experienced no pain whatsoever. A large quantity

of oxygen in the abdomen was liable to break up adhesions and, where the presence of the latter was suspected, as in a case of subdiaphragmatic abscess, they were especially careful not to inject too much. The point he wished to emphasize was that they individualized and had no hard and fast rules as to the quantity of the gas injected. Since their first experiments with this method they had made a number of changes in the technique, and they felt that had increased its safety and efficiency.

Pelvic Lavage for Pyelitis.—Dr. H. DAWSON FURNISS presented this contribution. He stated that the majority of acute cases of pyelitis coming under his observation were those following operation, and which were due to acute hematogenous infection. Usually the pyelitis was unilateral and followed six to ten or more days after operation. In the beginning the infection was located in the parenchyma of the kidney and the pyelitis and cystitis were secondary. Rest, local heat, and water copiously by mouth and rectum was the treatment first instituted. Lavage was not advocated until a week or ten days had elapsed, not because of any fear of harm, but because it was usually of no benefit in the early stage. However, he did not believe it advisable to wait too long in the topical treatment. Some had claimed that in lavage the chief benefit followed the dilatation, by the catheter, of some obstructed part of the ureter. In many instances, both acute and chronic, he had found dilatation of the kidney pelvis and ureter often, he believed, due to the obstruction caused by inflammatory swelling of the ureteral mucosa. The medicaments used in the lavage caused a subsidence of this and consequently less obstruction and better drainage. The results of lavage had been most encouraging. As a rule, the temperature became lowered within two or three days after the first one or two injections, and remained so; the cystitis improved and the urine promptly cleared. Often the cystitis was apparently worse than the pyelitis, yet dependent upon it. The time required to effect a cure depended upon the severity of the infection and the amount of ureteral and pelvic dilatation that had occurred. A case was not regarded as cured when there was more than the normal amount of urine in the ureter and pelvis, even though it was free of pus and bacteria. The greatest number of cases were the chronics, many of whom complained only of vesical symptoms. Before instillating treatment, stone and tuberculosis must be eliminated and it must be determined if there was a stricture of the ureter—a very common condition in women. If such a stricture were present its dilatation must precede or be done at the same time as the treatment of the pyelitis. The stricture cases must be followed up and dilated from time to time. Where movable kidney was a factor in bad drainage it must receive attention either by operation or corsetting. The results in the chronic cases had been equally as satisfactory as in the acute cases. The technique was as follows: The ureter was catheterized to the kidney pelvis. If there were obstruction it might be necessary to first pass a series of dilating bougies before it was possible to pass a catheter. The pelvis was drained of all urine either by allowing it to run or by aspirating with a syringe. The pelvis was then irrigated with boracic acid solution or sterile water and when clean all fluid was withdrawn. Then 1 to 5 c.c. of one-half per cent. silver nitrate was injected. In sensitive bladders it was better to fill them with saline solution for cystoscopy, as the silver nitrate that passed down the ureter was immediately rendered insoluble and nonirritating by becoming the chloride. It was an advantage to use a large catheter for its dilating effect and because the washing could be done so much more rapidly. Also it was better not to withdraw the cystoscope after the catheter had entered the pelvis, but to have a nurse hold it or immobilize it in a suitable holder. This prevented the catheter from slipping below the pelvis.

Dr. HAROLD BAILEY asked when it was practical to institute lavage. In the acute infections in pregnancy and in the early postpartum period to use lavage was rather dangerous and until the case became subacute, or chronic, other measures should be used, he believed.

Dr. FURNISS said that in the paper he had brought out the point that when one was dealing with an acute hematogenous infection he should wait a week or ten days, because the infection in the beginning was not in the pelvis of the kidney, but in the parenchyma. They did not regard lavage of the kidney for pyelitis as a dangerous procedure.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

NORTH CAROLINA BOARD OF MEDICAL EXAMINERS.

Raleigh, 1919.

(*Concluded from page* 130)

OBSTETRICS, GYNECOLOGY, AND PEDIATRICS.

1. What is meant by the science and art of obstetrics?
2. Give the boundaries of the true pelvis, mentioning the obstetrical landmarks found therein and state the diameters of its outlet.
3. Discuss the toxemia of pregnancy and outline its treatment.
4. What types of labor would indicate the employment of: (*a*) pituitrin, (*b*) forceps, (*c*) version, (*d*) "watchful waiting"?
5. What would be your management and method of treatment of: (*a*) placenta prævia, (*b*) retained placenta, (*c*) eclamptic seizures, (*d*) mastitis?
6. What is subinvolution, its principal causes and its treatment?
7. Mention the chief causes of painful menstruation and suggest the means of relief.
8. State the principal causes of convulsions in childhood and give the treatment for the same.
9. Outline the general treatment of enterocolitis in a child one year old, and write one prescription for the same.
10. What is spina bifida and what is its prognosis?

SURGERY.

1. Give the indications for and describe the methods of blood transfusion.
2. What are the causes of stricture of the esophagus? How would you manage a case?
3. Discuss the surgical diseases of the spleen.
4. (*a*) Give the treatment of a fractured patella; (*b*) the pathology and treatment of a sprained ankle.
5. Give the diagnosis and treatment of rupture of the bladder.
6. Name the neoplasms of the testis and treatment for each.
7. (*a*) How would you treat varicose veins of the lower extremity? (*b*) Give the etiology and treatment of thrombophlebitis of the femoral vein.
8. Outline your procedure in a pistol-shot wound of the abdomen.
9. (*a*) Mention the varieties and signs of cataract and the indications for operation; (*b*) name the nasal accessory sinuses and conditions due to their infection.
10. Define: diaphysis, leucoplakia, hypospadias, skiagraph, bronchoscopy, glossitis, osteomalacia, galactocele, sequestrotomy, pyelography.

ANSWERS.

OBSTETRICS, GYNECOLOGY, AND PEDIATRICS.

1. The *science of obstetrics* traces the physiological and pathological processes arising directly and indirectly from reproduction; the *art of obstetrics* is concerned with the necessary care and treatment of the woman and child in these various conditions.—(Berry Hart.)

2. The *true pelvis* is bounded *above* by a plane passing through iliopectineal line; in *front* by the pubic bones and the obturator membrane; *behind* by the concavity of the sacrum; *laterally* by the obturator membrane, the sacrosciatic ligaments and the internal surface of the acetabulum.

The *obstetrical landmarks* are: The iliopectineal line, symphysis pubis, and promontory of the sacrum.

The *diameters of the outlet* are: Antero-posterior, about five inches; oblique, about four and a half inches; transverse, about four inches.

3. *Toxemia of pregnancy* may be due to: "Uremia,

albuminuria, imperfect elimination of carbon dioxide by the lungs, medicinal poisons, septic infection; predisposing causes are renal disease and imperfect elimination by the skin, bowels, and kidneys.

"*Symptoms:* Headache, nausea, and vomiting, epigastric pain, vertigo, ringing in the ears, flashes of light or darkness, double vision, blindness, deafness, mental disturbance, defective memory, somnolence; symptoms easily explained by the circulation of toxic blood through the nerve centers. These may be preceded by lassitude, and accompanied by constipation or by diarrhea. Headache is perhaps the most significant and common warning symptom. In bad cases the urine is reduced in quantity (almost suppressed), very dark in color, its albumin greatly increased, so that it becomes solid on boiling. Next comes the final catastrophe of convulsions. The convulsive fit begins with twitching of the facial muscles, rolling and fixation of the eyeballs, puckering of the lips, fixation of the jaws, protrusion of the tongue, etc., soon followed by violent spasms of the muscles of the trunk and limbs, including those of respiration; hence lividity of the face and stertorous breathing, biting of the tongue, opisthotonus, etc. The fit lasts fifteen or twenty seconds, ending in partial or complete coma, possibly death; or consciousness may return, to be followed by other convulsions."—(King.)

Prophylactic treatment consists in the proper care and examination of the woman during pregnancy; metabolism must be kept as perfect as possible; the eliminative organs must be working; constant examination of the urine (for nitrogen output and presence of albumin) must be made; the diet must be regulated; headache, disturbed vision, nausea, edema must be investigated.

Active treatment consists in reducing the blood pressure; administration of purgatives, diuretics, and diaphoretics; administration of chloral, veratrum, or chloroform; and sometimes it is necessary to empty the uterus.

4. *Pituitrin* is indicated in cases of uterine inertia when the cervix is dilated or dilatable and there is no obstruction to delivery.

Indications for the use of forceps are: "1. *Forces at fault:* Inertia uteri in the presence of conditions likely to jeopardize the interests of mother and child. (*a*) Impending exhaustion; (*b*) arrest of head, from feeble pains. 2. *Passages at fault:* Moderate narrowing, 3¼ to 3¾ inches, true conjugate; moderate obstruction in the soft parts. 3. *Passenger at fault:* A.—Dystocia due to (*a*) occipitoposterior, (*b*) mentoanterior face, (*c*) breech arrested in cavity. B.—Evidence of fetal exhaustion (pulse above 160 or below 100 per minute). 4. Accidental complications: Hemorrhage; prolapsus funis; eclampsia. All acute or chronic diseases or complications in which immediate delivery is required in the interest of mother or child, or both."

Indications for version are: (1) In transverse presentations; (2) in placenta prævia; (3) in malpresentations of the head; (4) in simple flattened pelvis, and in minor degrees of pelvic contraction; (5) in prolapsed funis; (6) in sudden death of the mother, and (7) in any case where speedy delivery is imperative.

Watchful waiting is indicated in all cases not calling for active interference.

Treatment of placenta prævia: (1) Introduce one or two fingers within the os (the hand being in the vagina) and dissect the placenta from the uterine wall for about three inches from the os uteri in all directions, pushing it to one side if necessary. (2) Rupture the membranes, and if there is an unfavorable presentation turn the child and make the breech engage in the os; or, if the head presents forceps may be used if speedy delivery is necessary. Stop the hemorrhage by a tampon; this must be tight and thorough. *Accouchement forcé* is indicated; this consists of dilatation of cervix, version and immediate extraction of the child. The strength of the woman is then the main point to be cared for, and if in a reasonable time the uterus seems to be incompetent, the child may be delivered by art. In some cases of central placenta prævia, where rapid delivery is required, cesarean section may give good results for mother and child.

Delivery of retained placenta: "A finger—one or two—must be insinuated between the uterus and placenta at some point already partially separated, or, if no partial separation exists, at a point where the placental border is thick, and then passed to and fro, transversely, through the uteroplacental junction, acting like a sort of blunt paper knife, until separation be complete. Another mode is to find or make a margin of separation as before, and then peel up the placenta with the finger-ends, rolling the separated portion toward the palm of the hand upon the surface of the still adherent part. Great care is necessary to avoid peeling up an oblique layer of uterine muscular fiber, which might split deeper and deeper until leading the finger-ends through the uterine wall into the peritoneal cavity. Should such a splitting begin, leave it alone and recommence the separation at some other point on the placental margin. It is sometimes only possible to get the placenta away in pieces. These should be afterward put together and examined to indicate what remnants are left behind. It may be quite impracticable to get out every bit, but small remnants or thin layers too firmly adherent for removal do not distend the womb enough to create hemorrhage from their bulk, and subsequent danger of septicemia from their decomposition may be obviated by injecting warm (2 per cent.) creolin water into the uterus twice daily, until everything has come away."—(King's *Obstetrics.*)

Treatment of eclamptic seizures: Inhalation of ether and oxygen; chloral, veratrum, cathartics, diuretics, diaphoretics, hypodermoclysis; evacuation of uterus.

Treatment of mastitis: Treatment before suppuration occurs consists in supporting the breast with a bandage, emptying the gland regularly with a breast pump, and applying a belladonna plaster over the gland to stop the secretion and allay the pain. When pus is present an incision should be made at once, or the abscess may burrow extensively and riddle the breast. The incision should be made in a line radiating from the nipple, so as not to cut the ducts; it should be free, and all pockets opened up with the finger. Then a large drainage tube is inserted and shortened daily, as the wound heals by granulation. If necessary, several incisions are made.

Prophylactic measures consist in not touching the breasts (by doctor or nurse or patient) without thoroughly clean hands; by washing and drying the nipple before and after nursing, and by proper attention to hygienic conditions before labor, and the nipple and breasts being preserved from pressure.

6. When the uterus does not return to (approximately) its normal size and condition within about six weeks after labor, the condition is called *subinvolution. Subinvolution* is caused by fibroid tumors, pelvic inflammatory conditions, early resumption of sexual intercourse, premature rising from bed, retained secundines, uterine displacements and adhesions, etc. It is characterized by enlarged uterus and irregular bleeding. In all cases rest in bed, copious hot vaginal douches, abstinence from sexual intercourse, correction of constipation, and the administration of tonics are beneficial. Any treatment should be preceded by thorough curettage. Displacements should be corrected.

DYSMENORRHEA is painful menstruation. *Causes:* Pelvic congestion, pelvic inflammation, malnutrition, overwork, lack of development, neuralgia, stenosis, or obstruction of the cervix prolapse, or displacement of the uterus. *Treatment:* If possible remove cause; attend to the general condition, hygiene, tonics, regular habits, etc.; curettage may be necessary, and may have to be repeated (perhaps more than once).

8. CONVULSIONS IN CHILDHOOD.—*Causes:* Peripheral disturbances; "an apparently trivial cause such as psychic or sensory impressions resulting from unusual excitement in a child with an inherited unstable equilibrium, may produce a typical seizure. Foreign bodies in the nose or ears, traumatism, intestinal parasites, preputial abnormalities, improper or indigestible articles of food, poisons, and the toxemias resulting from or preceding certain diseases, as rachitis, malaria, or tetany, are among the causes producing convulsions. The organic causes are meningeal hemorrhages at the time of birth, tumors of the brain, cerebral abscess, hydrocephalus, and the various forms of inflammation of the brain or its coverings."

Treatment: "First overcome the attack or symptom. A mustard bath should be given. If the attack persists inhalations of a few drops of chloroform may be given and if there is any fever an ice-bag is placed to the head. Meanwhile a soapsuds enema is prepared and given on general principles. If there is an elevation of temperature, the enema may be given cool at 70° F. Examine the fecal discharge for a possible etiological factor as some foreign substance ingested or for intestinal parasites. Keep the room noiseless. Follow the enema by a rectal injection of the bromide of soda grains ten, and chloral hydrate grains three, for a five-year-old child, if the twitching still persists. When the child can swallow, calomel or castor oil is given to rid the intestinal canal of possible toxins."—(Chapin and Pisek's *Diseases of Children.*)

9. *Treatment of enterocolitis in a child one year old:* "An initial cleansing of the bowel with castor oil or calomel is imperative, followed by starvation for 12 to 24 hours. Egg albumin, barley water, or beef broth may be given. Equal parts of beef broth or barley gruel (1 oz. to the pint) are sometimes more acceptable. The tenesmus is relieved by the control of the diet and by the use of codeine, gr. 1/5 to ¼, or Dover's powder, gr. ½ to 2 grains every two or three hours, until the painful symptoms abate. Bismouth subnitrate, gr. 5 to 10, or bismuth subgallate, gr. 2, with powdered ipecac, gr. 1, may be given advantageously every two or three hours for the control of the mucus and blood in the stools. Whey is permitted when the stools show improvement, and after the acute symptoms have subsided sterilized milk is allowed in small amounts well diluted with barley or wheat-flour gruel. Last pasteurized milk is permitted with jellied gruels and broths. The prostration may require hypodermatic medication in the form of atropine, gr. 1/400 with strychnine sulph., gr. 1/250. As a daily routine, one saline irrigation at 100° F. serves a double purpose, as a cleansing solution and for absorption of part of the water. Strychnine sulphate, gr. 1/300, may be given as a tonic three times a day, and astringent enemas for the control of blood and mucus. Silver nitrate (1/1000) or a starch paste in less severe cases may serve the latter purpose. They should not be given more than once daily, and discontinued if the effect is not satisfactory. Too frequent irrigations often cause irritation and aggravations of the symptoms. Removal to the seaside or cool mountain air is a great help in the management, particularly in the convalescent stage."—(Chapin and Pisek's *Diseases of Children.*)

℞ Pulv. ipecac et opii gr. x.
Ft. in chart. No. x.
Sig.: One powder q. 2. h.

10. *Spina bifida* is a condition due to imperfect development, in which the posterior wall of the spinal canal is defective; membranes and cord may protrude. As a rule, the child dies within a few years; the great majority die within a few weeks or months of birth from escape of the cerebrospinal fluid or from septic meningitis.

SURGERY.

1. *Indications for blood transfusion:* Shock, hemorrhage, hemophilia, pernicious anemia, various infections and intoxications.

Methods of blood transfusion: (1) Direct (mediate and immediate); (2) Indirect (with and without the use of anticoagulants).

Transfusion of blood: "Crile has recently revived direct transfusion by anastomosing the radial artery of one individual with any convenient superficial vein of another. Under local anesthesia both artery and vein are exposed, tied below, and secured with an arterial clamp above. Each is then cut above the ligature and the adventitia of the central end pulled down and snipped off with scissors. The vessels may then be united by the Carrel method. Crile uses a little tube which has two grooves in its outer surface. The central end of the vein is pulled through the tube, turned back over it like a cuff, and held in place by a ligature which is tied in the second groove. The artery is next drawn over the everted vein and secured by a ligature in the first groove. The clamps are then removed and the anastomosis covered with a hot moist sponge, to relax the artery. The time the blood is allowed to flow depends upn the effects noted, but is usually from 20 to 40 minutes. In acute hemorrhage and shock and in pathological hemorrhage direct transfusion has proved of value, but in blood diseases and toxemias it seems of little use. As there is some danger of hemolysis and agglutination the effect of the donor's blood upon that of the recipient should always be studied before transfusion. If, owing to lack of facilities or time (the hemolytic test occupies 24 hours), this cannot be done, intravenous infusion of salt solution should be employed. Tranfusion may, of course, be performed later if such seems to be indicated."—(Stewart's *Surgery.*)

2. STRICTURE OF ESOPHAGUS.—*Causes:* Healing of a syphilitic or tuberculous ulcer, swallowing of caustic fluids, or boiling water, traumatism, malignant growths; the condition may also be spasmodic or hysterical. *Treatment:* The following methods have been employed, gradual dilatation, forcible dilatation or divulsion, electrolysis, internal esophagotomy, external esophagotomy, and (in case of malignant disease) gastrostomy.

3. SURGICAL DISEASES OF THE SPLEEN.—*Abscess* is usually metastatic, arising from a septic embolus in the course of an acute fever; the symptoms are rapid enlargement, with abdominal tenderness and rigidity in the left hypochondrium; treatment consists in drainage of the abscess if it is adherent to the parietes, and removal of the spleen if non-adherent. *Tuberculosis* rarely affects the spleen alone; splenectomy has been followed by good results. *Cysts* should be treated by splenectomy. *Tumors* of the spleen; sarcomata are the only primary new growths; splenectomy is the treatment.—(From Groves's *Synopsis of Surgery.*)

4. FRACTURE OF PATELLA.—*Treatment:* The best method is open operation, and wiring four or five days after the accident; for only by this means can bony union be obtained. The obstacles to bony union, without open operation, are that the tilting of the lower fragment cannot be overcome in any other way; the aponeurosis cannot be removed from between the fragments, nor the blood-clot from the joint, except by slow absorption. If no operation is done the union is fibrous, and the fibrous bond will stretch unless the patient be condemned to a stiff knee for six to twelve months. A working man is badly off with either a stiff knee for that time or a stretched bond forever.

The *open operation* must necessarily be aseptic. The knee may be washed out with 1 in 40 carbolic or 1 in 2,000 bichloride without injury, or sterilized saline solution may be used. The joint is opened by a horseshoe incision, the blood-clot is removed, the aponeurosis clipped away, the bones drilled and fixed in accurate apposition with silver wire, and the wound is closed without drainage. As atrophy of the quadriceps occurs early, massage and passive movements must be begun in ten days. The patient may go about on crutches in three weeks. Bony union is firm in six weeks.—(*Aids to Surgery.*)

The *possible traumatisms in a sprain of the ankle* are: Rupture of one or more ligaments, bruising of the synovial membrane, loosening or separation of cartilages, hemorrhage into the joint and surrounding tissues, laceration or displacement or stretching of muscles and tendons, injury to vessels and nerves, contusion of the skin, and sometimes separation of a piece of bone.

Treatment: "Sprains are best treated by early massage and movement, combined with firm, elastic pressure. In the ankle, for example, massage should be commenced at once, the part being gently stroked upward. The process is painful for the first few minutes, but soon ceases to be so and becomes soothing. The rubbing is continued for from 15 to 20 minutes, the patient being encouraged to move the toes and ankle. A moderately firm elastic bandage or strips of adhesive plaster are then applied, care being taken not to constrict the limb and so interfere with the circulation. The massage is repeated once or twice a day, the sittings lasting for about half an hour. The patient should be encouraged to move the joint from the first, beginning with the movements that put least strain upon the damaged ligaments, and gradually increasing the range. In the course of a few days he is encouraged to walk, or otherwise to use the joint without subjecting it to strain. Alternate hot and cold douching, or hot-air baths, followed by massage, are also useful. Complete rest and prolonged immobilization are to be condemned."—(Thomson and Miles's *Surgery.*)

5. *Intraperitoneal rupture of the bladder* involves the superior or posterior surface. The symptoms consist of shock and local pain. There is constant desire to micturate, nothing being passed except perhaps a little blood. Fatal peritonitis follows unless early treatment be adopted. A little blood-stained urine is usually withdrawn by passing a metal catheter, and the rent may be felt. A measured quantity of boracic lotion should be injected; if a rupture exists, the amount returned is considerably less than that injected. *Treatment* consists in immediate laparotomy, sponging out the fluid, and suturing the rent with a double row of stitches, through the serous and muscular coats, but avoiding the mucous coat. Trendelenburg's position is useful after the fluid has been removed. A catheter is tied in for the first three days, or the urine is drawn off at frequent intervals by catheter.—(*Aids to Surgery.*)

6. *Tumors of the testis* are exceedingly difficult to classify, either on a pathological or on a clinical basis. This arises from the fact that some varieties are composed of several different histological elements, no one of which predominates sufficiently to characterize the growth, and that other varieties show a marked tendency to undergo cystic and other forms of degeneration, and so to lose their original characters. Another peculiarity of testicular tumors is that they are specially prone to malignant transformation, so that a tumor which is originally innocent may eventually infect adjacent glands and become disseminated in distant parts of the body. Some of the varieties met with are very rare, for example, fibroma, myxoma, myoma, osteoma, and teratoma. In all these varieties the treatment consists in removing the testis. Others, such as adenoma and the different varieties of chondroma, seldom occur except in combination with sarcomatous elements, and are therefore most conveniently included among malignant growths (sarcoma and carcinoma); though treatment for these is castration as soon as the diagnosis is made. If the cord or scrotum is involved, the affected parts should be removed.—(From Thomson and Miles's *Surgery.*)

7. *Varicose veins of the lower extremity* may be treated by removal of the pressure and avoidance of any posture apt to cause and perpetuate the condition, together with the use of a woven silk or porous elastic bandage applied before getting up in the morning. Operation is often indicated; there are various forms of operation, all of which aim at the obliteration of the involved vein. Trendelenburg advocates the removal of three or four inches of the internal saphenous vein in the upper part of the thigh after a ligature has been placed at the top and bottom of the exposed portion. All tributary branches should be tied. The usual plan now is to remove the entire internal saphenous vein.—(From Barnett's *Textbook of Surgery.*)

THROMBO-PHLEBITIS OF THE FEMORAL VEIN.—*Etiology*: It is more apt to occur in patients who are debilitated or anemic or who have been confined to bed for a long time; or after certain operations, such as herniotomy, prostatectomy, or for appendicitis; or it may begin as a periphlebitis arising in connection with some focus of infection in the adjacent tissues.

Treatment: The patient must be placed at absolute rest, with the foot of the bed raised on blocks 10 or 12 inches high, and the limb immobilized by sandbags or splints. It is necessary to avoid handling the parts, lest the clot be displaced and embolism occur. To avoid frequent movement of the limb, the necessary dressings should be kept in position by means of a many-tailed rather than a roller bandage. To relieve the pain, warm fomentations, or lead and opium lotion, should be applied. Later, glycerin and belladonna, or ichthyol glycerin may be substituted. When, at he end of three weeks, the danger of embolism is past, douching and gentle massage may be employed to disperse the edema; and when the patient gets up he should wear a supporting elastic bandage. Amputation may be necessary in some cases.—(From Thomson and Miles's *Surgery*)

8. *Gunshot wound of the abdomen.* "The treatment, even without symptoms of visceral injury, is immediate enlargement of the wound, in order to explore the abdomen, check hemorrhage, and close such visceral perforations as may be found. The abdomen is then flushed with salt solution, and closed or drained, according to the amount of soiling present. If the omentum protrudes it should be ligated and removed, while coils of intestine should be carefully washed with salt solution and returned to the cavity. In cases in which there is doubt as to whether or not a wound enters the peritoneal cavity, such wound should be enlarged and the diagnosis positively made, preparation being made at the same time to treat any visceral injuries that may be found. In gunshot wounds on the battle field an exception has been made to the rule of immediate exploration, because it has been found that the chances of recovery are somewhat better without than with the operation undertaken in the absence of proper facilities."—(Stewart's *Surgery.*)

9. CATARACT is any opacity of the lens or its capsule.

Varieties: "Cataracts may be divided into: 1. *Primary*, when independent of any other ocular disorder, and (2) *Secondary* or *complicated*, when accompanying or following some other disease of the eye, such as glaucoma, uveitis, etc.

Cataracts are divided according to the *part of the lens involved* into: (1) *Lenticular*, situated in the substance of the lens. (2) *Capsular*, affecting the capsule. (3) *Capsulo-lenticular*, involving both lens and capsule. They are also known as: (1) *Partial*, limited to some part of the lens. (2) *Complete*, involving the whole lens. (3) *Stationary*, when they remain incomplete. (4) *Progressive*, spreading, tending to affect whole lens. *Stationary cataracts* may be divided into: (1) *Anterior polar.* (2) *Posterior polar.* (3) *Lamellar.* (4) *Various uncommon forms. Progressive cataracts* may be divided into: (1) *Senile* (cortical, nuclear). (2) *Congenital* and *juvenile.* (3) *Traumatic.* In patients *under* 35 all cataracts are of *soft* consistence throughout and *white* in color; such cataracts have no hard nucleus and are known as *soft cataracts. After this period*, the nucleus becomes *hard* and of a yellowish tint, and the lenticular opacity is known as *hard cataract.*

Treatment: Senile cataracts require extraction of the lens, with or without iridectomy; in congenital and juvenile complete cataracts, discission or needling is indicated; for traumatic cataract, extraction may be required; for stationary cataracts, iridectomy, discission or extraction may be indicated.—(From May's *Diseases of the Eye.*)

The nasal accessory sinuses are: Frontal sinuses, ethmoidal sinuses, sphenoidal sinuses, and maxillary sinuses (antrum of Highmore).

Conditions which may be due to their infection include: Orbital abscess, exophthalmos, conjunctivitis, edema of eyelids, epiphora, ptosis, paralysis of one or more of the muscles of the eye, blindness, inflammation of various parts of the eye, meningitis, phlebitis and thrombosis of the sinuses of the dura, cerebral abscess, nasal polypi, headache, neuralgia, vertigo.

10. *Diaphysis* is the shaft of a long bone.

Leucoplakia is a condition in which the tongue (or other mucous surface) has white patches on its surface.

Hypospadias is a condition in which the urethra opens on the under surface of the penis.

Skiagraph is an *x*-ray photograph.

Bronchoscopy is inspection of the interior of a bronchus.

Glossitis is inflammation of the tongue.

Osteomalacia is a condition characterized by softening of the bones.

Galactocele is a retention cyst due to closure of a milk-duct.

Sequestrotomy is the operation of removing a dead piece of bone.

Pyelography is an *x*-ray picture of a ureter and the pelvis of a kidney when these latter have been filled with a solution of a silver salt.

Euphorbia Serpens as a Dechloridizer.—Galdos calls attention to this powerful diuretic in dropsical conditions due to chloride retention. Its action is not due to any cardiotonic property. It is indicated in essential and symptomatic parenchymatous nephritis and should be exhibited in conjunction with sparteine or strophanthin. It is an excellent substitute for theobromine.

Miscellany

Health Work in Jerusalem.—The report of the war-time activities of the Jewish Health Bureau, established by Nathan Straus in Jerusalem, was recently received by the Zionist Organization of America. The period covered by the report is from September, 1914, to December, 1918. According to the report the Bacteriological Department was of the greatest service to the population of Jerusalem during the terrible epidemics of cholera, dysentery, malaria, and scarlet fever. Large quantities of anti-cholera and anti-typhus lymph were produced. In five different districts clinics were opened where free injections were given to all comers, without distinction of race or creed. The Bacteriological Department carried out 27,290 examinations during the period covered by the report. It provided 1,491,962 cubic centimeters of cholera lymph, and 238,800 cubic centimeters of typhus lymph. It administered 30,750 preventive injections against cholera. The Hygienic and Malaria Department examined the blood of 38,380 persons, and provided 154,115 kilograms of quinine. The Department for Eye Diseases discharged 441,874 visits to its clinics. In the department's hospital 436 severe operations were carried out. Patients passed a total of 6,042 days in the hospital. Many other phases of work were carried on, not only in Jerusalem but in all the towns of Palestine and among all the colonies within the scope of its activity.

A Franco-Jugoslavic Medical Entente.—During the late war a complete confraternity was established between the French and Servian soldiers. This was maintained up to the final act in the war drama of realization of Jugoslavic unity. On two separate occasions French medical men went to Servia to collaborate with Servian physicians. The first of these missons was in 1915 when a hundred French physicians went to combat typhus and of this number one-half succumbed to the disease. The second time was in 1916 when the Servian army had been almost miraculously saved from the disastrous retreat into Albania; during the reorganization in Chalcidika another body of French doctors was sent to safeguard the health of this army, and eventually the latter was active in a victorious offensive. In addition a French ambulance and hospital service was maintained on the Salonican and Macedonian fronts. The new kingdom is composed of Servians, Croatians, and Slovenians, comprises 15,000,000 inhabitants, and is destined to be a grand State; only during the period of reconstruction will it require outside aid. For a time its students will have to go abroad and its schools will welcome foreign professors. A rapprochement with Austria and Germany is unthinkable for many years to come and the new State will doubtless look to France. In Paris the students from the countries which constitute the new State as well as the graduate medical men who are studying and practising in France have formed a society known as the Franco-Jugoslavic Medical Union. Distinguished French physicians, such as Widal and Roger, are actively interested in the movement and a propaganda committee of native physicians has been appointed with headquarters in Paris and an affiliated branch will be constituted in Jugoslavia.—*La Presse Médicale* (xxvii, 73).

Italy as a Medical Center.—The disappearance of Germany and Austria-Hungary as post-graduate medical centers for Americans will naturally redound to the advantage of the home institutions, and, for those who will go abroad in any case, of those of Great Britain and France. It is quite possible that Italy may loom up in the near future and an impetus in this direction seems to have been given by an American army surgeon, Dr. Moore, whose article on medical Italy has been reviewed in *Il Policlinico* for November 2, 1919, xxvi, 44. Dr. Moore, who was agreeably surprised at the progressive condition of the medical and sanitary sciences in Italy, enthusiastically recommends the latter country for post-graduate studies. The Italian author of the article in the Policlino marvels in his turn over the wonder of the transatlantic visitor, and this attitude is not surprising, for the well informed medical man who has access to Italian periodicals and is able to read them certainly knows well that Italy borrows little in comparison with the amount of original work which emanates from the numerous centers of medical learning in that country. For years the MEDICAL RECORD has endeavored to give to Italy full credit, especially in its editorial columns, for its numerous contributions to medical progress. Apparently language is the sole barrier. Few Americans know Italian and Italians as a class do not know English.

Invention for Armless Soldiers.—A Scottish plumber, according to press dispatches from London, has invented a machine which enables armless soldiers to eat, drink, light cigarettes and play dulcimers. The extreme simplicity of construction and manipulation is said to be the striking feature of the invention. A few steel wires are set in a frame and two arms like big spiders' legs are attached to the table. The armless man works the two miniature cranes by pressing his stockinged feet on the two treadles. The operation is thus described:

There is a cleavage in the stockings between the big toe and the rest of the foot, enabling his right foot to rest on two bars of the treadle and clutch a bar. Thus while the treadle itself swings the crane backward and forward over the surface of the table the third bar, acting by springs, makes a grip of the clutch or releases objects. The left hand crane is much simpler, ending in a splay footed hoof with a thumb in the middle. At a pressure of the treadle the thumb automatically drops ready to seize a biscuit or fork. While the right hand crane clutches a bowl of soup, the hoof plunges the spoon in and offers it to the diner's mouth. While the hoof digs a fork into a piece of meat, the other clutch cuts it up. The right hand clutch pops a cigarette into the diner's mouth and then strikes a match on the table and lights it and follows this up by playing on the dulcimer.

One form of activity not executed by these arms is shaving, but there seems to be no reason why they should not work a safety razor.

BRONCHOSCOPIC TREATMENT OF BRONCHIECTASIS AND PULMONARY ABSCESS.*

BY HENRY LOWNDES LYNAH, M.D.,

NEW YORK.

BY the use of the bronchoscope in the treatment of bronchiectasis and pulmonary abscess many patients suffering from these conditions may not only be relieved, but even cured by the establishing of proper drainage of the lung.

In bronchiectasis, especially in cases following diphtheritic involvement of the bronchi, there is a marked peribronchial infiltration and connective-tissue thickening of the bronchial wall which often produces stenosis by subsequent contraction. These bronchial stenoses not only follow diphtheritic tracheobronchitis, but may also follow the sojourn of foreign bodies for a long period, influenza, syphilis, and other conditions in the mediastinum causing pressure from without, as in peribronchial infiltrations and mediastinal glandular pressure. Pressure from without the bronchus is often productive of a chronic inflammatory thickening of the compressed bronchial wall, which may cause stenosis later.

In intubated cases suffering from laryngeal diphtheria with obstruction of the lumen of the intubation tube, secretions may be retained in the lungs, and produce a "sponge soaking" of the lung structure, and the patient, being unable to expel this secretion from the lung, frequently succumbs. Such cases are frequently diagnosed bronchopneumonia, but the so-called bronchopneumonia is rapidly relieved by bronchoscopic evacuation of the secretion. As soon as proper pulmonary drainage is established, the condition of the patient improves. (Fig. 1.)

In peanut bronchitis following the inhalation of a peanut kernel or particles of masticated peanut, a very severe reaction follows, and an enormous amount of secretion is produced by the irritant action of the peanut. If the peanut kernel or particles are not removed there is such retention and "sponge soaking" of the lung, with foul secretion, that the child succumbs later to pulmonary abscess and septicemia. (Fig. 2.) A child three years of age who inhaled many small pieces of peanut pulp into the right bronchus suffered from a severe bronchitis following the accident, and was sent to the hospital the following day for treatment. There was considerable difficulty with expiration, and a marked asthmatic wheeze was audible at some distance. The bronchoscope was introduced, and many pieces of peanut were removed by forceps and suction. The condition of the child improved after the removal of the peanut fragments, but physical examination showed that little air entered the lower posterior portion of the lung. The following day the posterior branch of the right lower lobe bronchus was explored, a 4 mm. bronchoscope being used. Some foul smelling pus was sucked out from this region, but no fragment of peanut was found, and the aeration of the lower lobe of the lung did not improve to stethescopic examination while the bronchoscope was *in situ*. Unfortunately a small piece of the peanut had lodged in a small dorsal branch of the right lower lobe bronchus, which I was unable to locate and remove. The small piece of peanut had disentegrated, and had produced a septic bronchitis three days after the accident. The abscess ruptured into the pleura, and was drained by rib resection. The child succumbed six weeks later from pulmonary abscess and general septicemia.

FIG. 1.—Radiograph of a patient intubated for laryngeal diphtheria. The lumen of the intubation tube became obstructed, which caused retention of secretion and "sponge soaking" of the lungs. The dark triangular area in both lungs is the gradual "sponge soaking" from below upward. The condition was diagnosed bronchopneumonia, but was promptly relieved after the removal of the tube and bronchoscopic evacuation of the retained secretion.

This is usually the unfortunate termination following the aspiration of extremely irritating substances such as food and nuts, especially when a small particle is deeply lodged in a small branch bronchus which is beyond the range of the broncho-

*Read before the New York Academy of Medicine, Section on Medicine, November 18, 1919.

scope. The secretions become purulent within a short time, and lung abscess is the inevitable result. This is frequently the starting point of bronchiestasis. The retention of secretions below a foreign body or bronchial stricture often follows, even after the

FIG. 2.—Radiograph of a purulent "sponge soaking" of the lung following the inhalation of a fragment of peanut kernel. Note the dark shadow in the region of the right lower lobe, in which a small particle of the peanut lodged. Several small pieces were removed bronchoscopically, but the fragment which remained produced septic pneumonia and pulmonary abscess.

successful removal of the foreign body, for the bronchus will necessarily dilate below the stricture and become a reservoir of foul secretion. A bronchial stricture, no matter how small the lumen may be, does not shut off the airway; but it does shut off the normal expulsion of secretions, and the retention of foul secretions for long duration will promote bronchiectasis lung abscess, or the lung may even become gangrenous. (Fig. 3.)

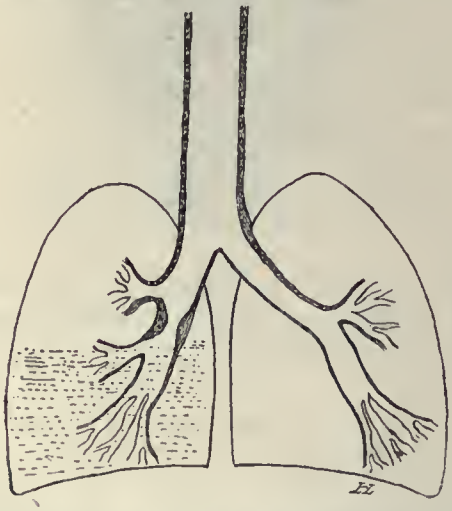

FIG. 3.—Schematic sketch of the tracheobronchial tree and lungs. The stenotic narrowing in the right stem bronchus illustrates the cause of bronchiectasis and "sponge soaking" of the lung from retained secretion. The dotted area in the right lung shows the retention of secretion up to the level of the stricture. Proper lung drainage bronchoscopically will relieve the condition.

Lung abscesses may be either diffuse or circumscribed. In the diffuse variety the lung is usually "sponge soaked" with pus, the removal of which bronchoscopically will greatly improve the patient. On the other hand, a circumscribed abscess may be extremely difficult to cure, especially when the abscess attached by its stalk is at a right angle to the bronchus into which it pours its contents. (Fig. 4.) If the stalk of the abscess connects in a line with the bronchus into which it empties, then it is not

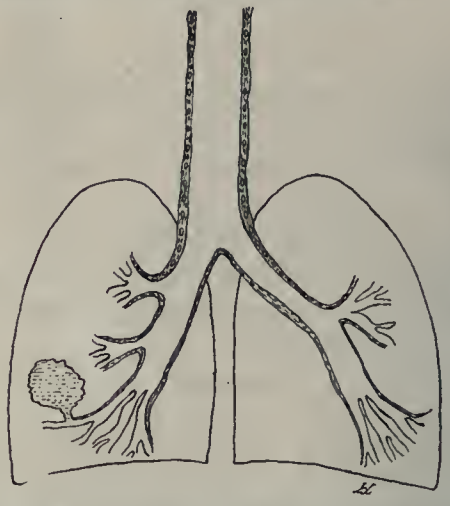

FIG. 4.—Schematic sketch illustrating the reason why circumscribed lung abscesses are difficult to drain. The small round dotted area in the right lower lobe is a lung abscess. Note that the stalk of the abscess connects with a branch bronchus at a right angle. It is difficult to get around the corner and enter the abscess cavity.

a difficult procedure to enter the abscess cavity and drain it properly, but a true circumscribed lung abscess is at times extremely difficult to cure. The method advised by Yankauer will relieve many of the conditions, for the infiltration of the solution will soften secretion and make expectoration of the thick pus much easier for the patient.

In the studies bronchoscopically of pulmonary abscess by the writer, pus is usually seen to be pouring from a small branch bronchus, and it has been

FIG. 5.—Radiograph of a lung abscess in the left lower lobe. The abscess cavity connected on a line with the branch bronchus into which it emptied, and the abscess cavity could be entered with a special five millimeter bronchoscope.

at times difficult to locate the definite abscess cavity in the lung from which the pus is oozing. However, in a case referred to the writer by Dr. Jesse G. M. Bullowa a definite abscess cavity was entered near the diaphragm by a specially made broncho-

scope, 5 mm. by 45 cm. in length. The abscess was well down toward the diaphragm, the stalk of the abscess connecting with a left lateral branch bronchus. The mouth of the stalk of the abscess was surrounded by granulation tissue, from the

FIG. 6.—Radiograph of the same case as shown in Fig. 5, after repeated washings of the abscess. The shadow in the left lower lobe has disappeared, and expectoration of pus ceased.

center of which foul smelling pus was oozing. The 5 mm. bronchoscope entered the abscess cavity through the connecting stalk, for it was on a line with the lip of the bronchoscope, and not around a corner. (Fig. 5.)

When the abscess cavity is connected by its stalk to a branch bronchus which can be entered with a small bronchoscope, it can be readily drained and washed, but many treatments are often necessary before the case is finally cured. In some instances there is considerable reaction following pulmonary washing; while in other cases there is little or no reaction or shock. In the young man referred to,

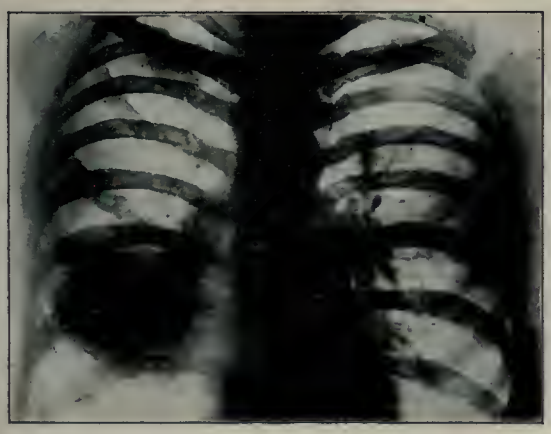

FIG. 7.—Radiograph of a pulmonary abscess the stalk of which was at a right angle to the branch bronchus into which it emptied. Note the dense shadow over the right lower lobe, with pus "sponge soaking" of the surrounding lung tissue.

there was a marked reaction after each treatment. His temperature rose to 105° F. one hour after each washing, and gradually fell to normal the following day. He also complained of much pain in the left chest in the region of the diaphragm. However, he made a complete recovery after a period of three months and has remained well ever since, one and a half years later. (Fig. 6.)

In another case, a man of twenty-two years, referred by Dr. Kupferman, had a pulmonary abscess

FIG. 8.—Radiograph of the same patient as pictured in Fig. 7, after seven lung washings. The density of the shadow has slightly decreased. The abscess cavity could not be entered by the special long bronchoscope, for it was around a corner.

of one and a half years' duration, following tonsillectomy and the inhalation of a piece of wooden tongue depressor. He had an abscess off at a right angle to the bronchus, into which it was emptying, and pus could only be seen oozing out of a small branch bronchus, and I was unable to enter any definite abscess cavity even with a 5 mm. bronchoscope. (Fig. 7.) However, the patient was apparently improved after seven washings, the fluid having softened the thick purulent expectoration which had been difficult to cough-up before treat-

FIG. 9.—Radiograph of the writer's method of drainage of a bronchiectatic cavity and pulmonary "sponge soaking." A long fenestrated soft rubber tube is used as the inner tube of the tracheal cannula. Little air entered the right lung until the tube opened the stricture and drained the "sponge soaked" area.

ment. The patient, unfortunately for him, decided that the weekly pulmonary washings were too slow in producing a cure, and he decided to have the abscess drained by thoracotomy. This was unsuccessful, for he succumbed shortly after the opera-

tion. The radiographs taken at the time of admission and after the last washing showed an apparent improvement. (Fig. 8.) There was also improvement in the amount of pus coughed up, and less odor. This case was one of the type of abscesses well off at a right angle to the bronchus into which it was emptying, and while I could see the mass of inflammatory granulation tissue at the mouth of the abscess stalk, I was unable to enter it with the small especially made bronchoscope. This is the reason why so many of the pulmonary abscesses are so extremely difficult to cure. The washing will soften secretion and promote easy expectoration, but it is by no manner of means a cure-all in long-standing cases when the cavity of the abscess cannot be reached. Bronchiectasis resulting from bronchial stenosis is much more readily dealt with by bronchial dilatation and drainage. In one instance the right bronchus was drained and the lung aerated by the introduction of a long soft fenestrated rubber inner tube into the right bronchus. There was a bronchial stenosis in this patient. She wore the soft rubber tracheobronchial tube for six months, and made a complete recovery. The patient is still alive and perfectly well, two and one-half years later. The bronchi may be intubated by the long bronchial intubation tubes of the writer, but the catheterization of the bronchi through the tracheotomy tube is tolerated much better by the patients, and at the same time they can have the use of the voice. (Fig. 9.)

Pulmonary drainage is difficult in all cases of circumscribed abscess, but I think the conservative bronchoscopic measures of treatment should be given a thorough trial first, before radical major surgery is attempted.

DILATATION AND PLICATION OF THE CAPUT COLI.*

By DOUGLAS H. STEWART, M.D., F.A.C.S.,
NEW YORK.

AT the external, terminal, or rectal end of the large intestine the longitudinal muscular fibers are arranged as a tube or pipe. At the internal terminal, dead-end, or cul-de-sac called the caput coli, such fibers form straps by being grouped into the bands known as tæniæ coli. The circular or napkin-ring fibers are annular tube-like structures generally; but they also at the cecum have portions that are gathered into what might be termed ring-strap taeniæ peculiar to themselves, that serve as reinforcements to soften constrictors. The whole arrangement is such that, taken together with the fact that longitudinal and circular bands are rather shorter than the limits of the extended or distended length or breadth of the colon which they cage, it leads to the shape or appearance called sacculation. This sacculation is but an evidence of extension and distension that are more or less restrained and kept within limitations by the combined curb of both transverse circular and longitudinal linear muscular fibers.

From the aforesaid it follows that the study of colonic movements is fascinating and confusing because it might appear to a superficial observer as though here was presented a proof of the persistence of a lawless force causing irregular or uncontrolled motion. The fact is that any such basic idea is contrary to science and to exact race experience, both of which take for granted that all forces must be law-abiding or must cease to be forces. All motion must be definitely controlled or must change to some other form that is controlled. Surely even the humblest mind that purchases one pound of groceries must grasp the fact that the pull of gravity upon that weight must be exactly what is termed "one pound." Which easily proven proposition includes the statement that since a force is unchanging, it must of necessity be law-abiding. Even so, the actions of the colonic muscles appear to be incoordinate. Some fibers extend themselves while others contract, as may be seen through the fluoroscope or as may be registered upon the plate that bears an actinogram. However, by careful methodical study one may come to discern that this matter, like all other manifestations of life, is governed by a clear rule of conduct. It only remains for the investigator to discover what that rule may be.

If it be admitted that propulsion of colonic contents is a result of colonic activity, then one thing at least will be found always the same. That is that during that act of progressive propulsion the longitudinal fibers are contracting; and this whether the circular fibers are contracting or expanding. So long as neither is passive one sacculus may be contracting while its neighbor may be expanding; but the longitudinal fibers are relaxed or extended during a period of inactivity, solely. When *both* sets of fibers are quiescent the limitations set by their length maintain the external appearance termed sacculation, and the internal aspect called pouches, buckets, or haustræ coli. (It is admitted at once that this is different from the teaching of textbooks.) A scheme consisting o a balloon that is well expanded, though confined within a circular birdcage, might furnish an idea of conditions as they are. In short, all the actions of the colonic muscles are so very curious in their manifestation that they could hardly fail of observation and of record. Yet all mention that the present writer has found is comprised within the intent of the words to be found upon page 381, paragraph 224, of Foster's Physiology, which read thus:

Fig. 1.—A normal cecum.

*First paper.

"Along the colon when the sacculæ are well developed, the movement may be described as intermittent from sacculus to sacculus, the contents of one sacculus being driven by the peristaltic contraction of circular fibers into the next sacculus which

Fig. 2.—Two semi-hernias, one spherical and one triangular

prepares to receive them by a relaxation of its circular fibers and a contraction of its longitudinal fibers."

The curious mechanism works as though pressure closes the ileocecal valve, and thus bars return flow of the semisolid colonic contents, while the long muscular strands pull various segments in sequence over or along those contents, while at the same time opposition to onward passage is lessened or removed by a sort of advance space or vacuum pump that is created through relaxation of succeeding empty distal circular muscular rings. At the same time, also, motion is insured by the contraction of the ring of circular fibers that surrounds the proximal saccular segment. But the segments are so banded together by or dependent upon the longitudinal straps that, should those straps fail, the whole machine would become impaired, dilated, extended, and inert, which conditions have but to reach a certain degree in order to become atonia coli, with its resultant stasis. The act of circular squeezing from a circumference inwards may produce motion of bowel contents in either or both directions at the same time; but the fixation and pull down of the longitudinal fibers, together with a shut ileocecal valve, determine a definite direction to any motion that is initiated. Or, in other words, circular fibers and their activity merely determine that there shall be motion even though it be but an agitation or churning. Direction is decided by the action of the longitudinal fibers in pulling an empty sacculus over the expelled contents of a full one. Surely the colon is one of the most remarkable machines in existence, but whether it could be imitated by man need not detain us, for it is very certain that no engineer will ever furnish toleration or employment for its nonmechanical principles.

The three bands of longitudinal fibers begin or take origin at their fixed point of traction at the appendix. How greatly the removal of the latter interferes with efficiency is an open question—one that would admit of much argument with rather indefinite conclusions. Clinically it appears like some other matters; that is quite on a par with some such question as "Do gallstones hurt?" The only answer to which is the evasive but accurate statement that all results depend upon the influence of preexisting circumstances. Clinically and at times it appears as though the interference or slowdown was marked to such a degree that on several occasions, when appendectomy did not yield the good results that should have followed that operative procedure, yet after several years (5 to 15) of discomfort and stasis, a good firm fixation of the taeniæ was followed by beneficial consequences to the extent of a satisfactory symptomatic cure, which fine terminal effect even a prior plication of the stomach had failed to procure, in one instance.

For clinical purposes the groups of the longitudinal fibers may be termed one anterior and two posterior; for purposes of explanation these may be considered as being placed at the angles of an isosceles triangle, and the spaces which they bound may also be termed triangular. From this conception it follows that the space between the anterior and the posterior internal band may be likened to an inverted letter A, the crosspiece of which might be imagined as the position of the ileocecal valve. The surfaces between the posterior internal and the posterior external band and between the latter and the anterior band may be compared to a capital W or two Vs placed side by side. A stitch from any one of these bands to its neighbor will tend to make an incompetent valve tighter. Such a stitch from the posterior external band will pull upon the outer or the inner end of the valve according to placement. The difficulty seemed to be in discovering why a stitch from the anterior to the posterior internal band and running parallel to the valve did

Fig. 3.—Internal and external linear semi-hernia.

not relax valvular tension. The only reason the writer can give for a contrary effect is that such a stitch jams the ileum further into the cecum, thereby exposing greater valve-leaf surface to the closing urge of the colonic back-pressure.

The question of which two bands shall be brought together or which shall be shortened resolves itself into a question of what change the operator thinks best to make in the given condition of affairs. Does he wish to shorten, to narrow, or to do both to the caput coli; does he wish to put tension on the internal end, on the external end, or upon both ends of the valve, or does he wish to jam the leaves of said valve further into the colon. The mechanics of all these matters are so simple that explanation need not detain us. In any event they are mentioned elsewhere.*

However, it may be well to repeat in this place that any and every stitch must begin and must end in a taenia, nor must any stitch cross a band. As may be easily seen upon trial, drawing of the taeniæ closer together both narrows and shortens the caput coli; but should additional shortening appear proper, then a modified mattress suture may be made to run longitudinally to any or all taeniæ in which case two or three short stitches are preferable to a single long one.

The valve of the colon will be found incompetent more often from malposition and distortion than from any distention or stress. Usually a distended colon is accompanied by a stretched-tight valve; but an appendix may be so bound by adhesions that the effect upon the valve is much like that of the finger introduced into the mouth and pulled sideways. Consequently the appendix should be removed for many reasons, and its stump should be ligated, inasmuch as it is the point of pull upon which the whole longitudinal musculature of the caput is dependent, and the correct action of those muscles is basic to the machine.

Placement of stitches is easy, so that one relies upon palpation or touch; for one who relies upon sight alone for his guidance never will discover where the wall of the colon has thinned. The bulgings between the tæniæ may be either domes, rugæ, or of mixed appearance. Examples are marked S. H. in the illustrations. When these were palpated in the living subject it became evident at once that they felt quite differently from other portions of the colonic wall, much as though there was a deficiency of resistance at certain places similar to what is felt in the instance of an incomplete hernia. When all such spaces were closed or reinforced by appropriate suturing the results were of the happiest nature.

The margins of the tæniæ are sometimes free edges, sometimes adherent. Their thickness or bulging or roundness and their flatness or smoothness or tape-like character differs in different subjects or even varies in various situations. But with a modification of the stitch usually credited to Sick, or with the glover's stitch, or with the ordinary interrupted form, any emergency may be met. In the dome-shaped bulgings the stitch should, in passing, dip lightly into the most prominent part of the bulge, lest when the stitch be drawn tight the dome slides from under its restraint and bulges out in a distorted form either above or below the restraining stitch.

ANGIOMA OF THE STOMACH.

By W. S. LEMON, M.D.,

ROCHESTER, MINN.

SECTION ON MEDICINE, MAYO CLINIC.

In this report, I wish to add one more case of angioma of the stomach to the five of which I have knowledge, namely, the cases reported by Guisez, Stockis, Burty, Lammers, and, recently, one by Sherril and Graves. The clinical aspect of the case

Fig. 1.—(Case A258233). Photograph of hemangioma of the stomach as it presented on the mucous surface.

came under my observation; it was studied pathologically by Dr. Broders, who examined the specimen at the time of operation.

Macroscopic Examination.—The tumor was irregular in shape, bluish-black, rather soft, having the feel of a mass of angle worms, and measured 6 by 5 by 5 cm. It was surrounded by a fibrous capsule ranging from 1 to 2 mm. in thickness. Bands of fibrous tissue between the dark angiomatous areas made it appear not unlike an anthracotic lung. The tumor lay between the mucosa and serosa, and in places it had broken through its cap-

Fig. 2.—(Case A258233). Photograph of hemangioma of the stomach after section. Note its marked lung-like appearance.

sule and penetrated the surrounding structures (Figs. 1 and 2).

Microscopic Examination.—The mass was made up of a network of capillaries, some showing a fairly marked dilatation. Blood pigment could be

seen both within and without the capillaries. Some fields were entirely of angiomatous tissue, while others showed muscle with small groups of capillaries. A few clusters of lymphocytes were found

FIG. 3.—(Case A258233). Photomicrograph of hemangioma of the stomach, showing a network of capillaries (X50).

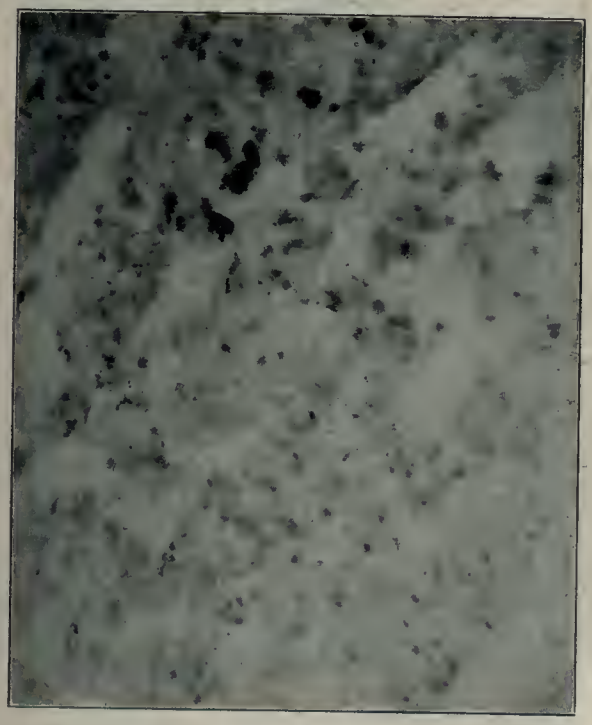

FIG. 4.—(Case A258233). Photomicrograph of hemangioma of the stomach, showing patches of blood pigment in the capillaries (X250).

in some of the fields. A diagnosis of capillary hemangioma was made (Figs. 3 and 4).

History of the Patient.—Case A258233.—Jan. 28, 1919, a man, aged 67, presented himself for examination, complaining of distress in the epigastric region. The patient was a large man, fully six feet tall, and weighed 202 pounds, although he showed but slight evidence of adiposity. His habits of life were exemplary and his trouble could not be traced to any indiscretion or excess. The previous history was unimportant. Six years before he had had two minor opera-

FIG. 5.—(Case A258233). *X*-ray of chest showing dilated aorta.

FIG. 6.—(Case A258233). *X*-ray of stomach showing filling defect.

tions, the correction of a varicocele, and the removal of an epithelioma of the lip. After the removal of the epithelioma he had been treated for several months by the *x*-ray; there had been no evidence of recurrence.

His gastric trouble had extended over a period of

about six months; it had been initiated by an exhausting, but not painful, diarrhea. The stool was "tarry" and contained much blood. Following this attack and two months before his present examination, he had felt an indefinite aching pain located at the left costal arch and sufficiently urgent and persistent to cause wakefulness and to make work almost impossible. The pain had taken on a diffuse character and radiated downward and inward toward the lower quadrants.

Dietetic treatment had been advised, milk being used as a basis, but this increased rather than lessened the distress. A barium meal, taken when an *x*-ray plate was made, proved to give him great comfort. This meal was repeated at the end of a week. The *x*-ray plates of the stomach showed a large unfilled area in the fundus and the splenic flexure of the colon seemed fixed out of its normal position. The descending aorta was considerably dilated and was thought to have been so for many years, as a cough during that time had suggested pressure on the recurrent laryngeal nerve.

Two weeks before examination, the patient had been conscious of some indefinite pain, located at the right costal margin, but his appetite had been good, and food taken relieved rather than distressed, although a certain sense of fullness with discomfort was commencing. He had had, however, no vomiting and no hemorrhage by mouth and there had never been urgent colic nor jaundice. He had lost twenty-five pounds in weight, was dyspneic on exertion and easily fatigued, and had had a slight cyanosis.

Physical examination revealed a loose skin, muscles somewhat atonic, and a loose and pendulent abdomen, adiposity 2 on a scale of 4, cyanosis 1, a well marked arcus senilis, and arteriosclerosis 3. The systolic blood pressure was from 220 to 240; the diastolic pressure remained constant at 120. The urine was normal with the exception of albumin 2, and hyaline casts 1. The pulse was 72 and regular. Examination of the mouth, nose, and throat revealed oral sepsis and several carious teeth. Increased areas of dullness beneath the sternum and marked left ventricular hypertrophy were found, although the heart sounds were clear, without irregularity, and the heart itself was compensating satisfactorily. The lungs were clear, the liver was not enlarged, and there was no evidence of edema in the extremities. The epigastric area was carefully examined by several consultants; there was no evidence of palpable tumor nor other abnormality. The highest readings made during the fractional examination of gastric contents gave a total acidity of 50 per cent. and a free acidity of 30 per cent.

The roentgenographic studies were interesting in that they confirmed previous examinations, namely, an aneurysmal dilatation of the aorta (Fig. 5), the thoracic aorta taking on the appearance of a conical sac-like body, and a filling defect in the body of the stomach which the roentgenologist believed to be caused by a cancerous growth, the operability of which was questionable because of its location (Fig. 6). The one difference in the *x*-ray examination made at this clinic from that made elsewhere was the finding of what appeared to be a normal colon, the displacement of the splenic flexure not being confirmed.

The roentgenologist's diagnosis of cancer of the stomach was confirmed clinically, but in view of its location, the marked hypertension, and the advanced age of the patient, surgical intervention was not advised. The patient, a surgeon himself, realizing that an exploration promised him little, at first chose not to have an operation. After several days' consideration, however, he determined to take what little chance of improvement there might be.

At operation, February 5 (W. J. Mayo), a tumor 6 by 5 by 5 cm., which pathologic examination proved to be an angioma, was found lying in the fundus of the stomach; it was quite freely movable and presented easily. About 11 cm. of the center of the stomach were removed, a sleeve resection and an end-to-end anastomosis made.

The convalescence was uneventful; the patient returned to his home on the second of March, twenty-five days after operation, with the wound healed. Two months later he reported that so far as the operation was concerned, everything had been "eminently satisfactory." He had a very good appetite and was able to eat almost everything and his early distress from sour fermenting stomach had improved materially. Six months after operation he was enjoying good health and was engaged in his medical practice.

A CASE OF CONGENITAL HEMI-HYPERTROPHIA TOTALIS.

By H. R. COSTON, M.D.,

BIRMINGHAM, ALA.

PHYSICIAN TO MERCY HOME, ETC.

THE patient, R. S., male, age twenty-two months, is the fourth child of healthy parents, of rather low mentality. The other three children are normal and healthy, and mentally above their parents. This one has never been sick, and seemingly is of good mentality. The mother was well during her pregnancy. I know the family from the great-grandmother down to this child,

FIG. 1.—Front view of the baby.

and there is no history of defective development in any member of the family, except a second cousin of this child's, on the mother's side, who has six toes on his right foot.

The great-grandmother, now hearty at the age of seventy-nine, says positively there was no idiocy, in-

sanity, epilepsy, or deformity in any other member of the family, back to her grandparents. This gives a history through six generations, with only one cousin and this case, in any way physically defective.

This child was born after a very quick and easy labor. It was observed immediately upon his birth that

Fig. 2.—Roentgenograph of the hands.

one side was much larger than the other. Indeed, I remarked to the great-grandmother, who was in the room when the child was born, that his right side was a ten-pound baby, and his left a seven-pound baby.

An attempt was made, when he was only two weeks old, to secure *x*-ray pictures, but the result was not satisfactory. Recently, Dr. W. C. Montgomery made some pictures, three of which are here reproduced.

The following are some measurements, which I have made lately:

Side of head: right, 10½ inches; left, 9¾ inches.

Top of head to upper border of ear: right, 6 inches; left, 5½ inches.

Chin to Occiput: right, 11¼ inches; left, 10¼ inches.

Chest: right side, 10½ inches; left side, 9 inches.

Middle of thigh: right, 9½ inches; left, 8 inches.

Calf: right 7¼ inches; left, 6¾ inches.

Foot: right, 6 inches; left, 5 inches.

Anterior-superior spine of ilium to external malleolus: right, 15 inches; left, 13 inches.

Acromion to tip of fingers: right, 13½ inches; left, 12 inches.

Around hand: right, 4¾ inches; left, 4¼ inches.

There is no defect of eyes nor defective development of any individual limb or organ. The skin is normal, and the eyes are alike.

In almost all classical cases the hypertrophy is on the right side. There are a number of cases of only partial hypertrophy—confined to one side of the face, or to a single limb; occasionally cross cases are seen, on one side of the face, and one or more limbs on the other side.

Differential Diagnosis: Acromegaly is bilateral, is confined to hands, face, and feet, and is not congenital. The broad face and great mental hebitude distinguish myxedema, which develops late in life. Hemiatrophy should give little difficulty in diagnosis, the prominence of the bones, the wasted and weak state of the muscles will serve to diagnose this condition. Sporadic cretinism and the various paralytic conditions should offer very little difficulty in diagnosis.

There is no treatment other than to put an extension shoe on the short leg.

AMAUROTIC FAMILY IDIOCY OR INFANTILE AMAUROTIC IDIOCY.

By J. EPSTEIN, M.D.,

NEW YORK.

Amaurotic family idiocy is a disease of early infancy. It has an unknown etiology, a definite pathology, a uniform clinical course, and a fatal prognosis. It is chiefly characterized by an early decay of body and mind, blindness, and death. Various names were given to this disease of which amaurotic family idocy, Tay-Sachs disease, infantile cerebral degeneration with symmetrical changes in the macula lutea, and primary amaurotic mental deficiency are best known. But infantile amaurotic idiocy would perhaps be more descriptive of this disease, because it occurs only in infants, amaurosis is always present, and idiocy is a constant symptom. It is an uncommon malady and for some obscure reason it affects almost exclusively Jewish children of Russian or Polish parentage. In many cases more than one child in a family is affected.

The etiology of this remarkable disease is unknown. The age of the parents, the number of children in the family, and their order of birth have no direct influence. Marked neurotic taint in the family, blood relationship between the parents, traumatic injury to the pregnant mother, and toxemia in the child have all been assigned among the causes of this mysterious disease.

The pathology is fairly definite. It is a disease of the central nervous system consisting of a degeneration and disintegration of the nerve cells of the brain and spinal cord, leading to neuromuscular weakness, mental deterioration, blindness and death. There is probably a primary cessation of development of the central nervous system and a secondary gradual destruction of the nerve cells.

The symptomatology is that of physical and mental retrogression. An apparently normal healthy baby at birth, begins at about the age of six months to show evidence of general backward-

ness. The normal developmental progress of infancy ceases and a gradual decadence takes place. The baby loses the power to hold up the head, cannot sit up or carry out properly the usual motor functions of early life. It becomes oblivious to

Fig. 1.—Case I, V.S., an amaurotic family idiot, 15 months old.

its surroundings and the face assumes a dull, vacant, aimless, idiotic expression as is shown in Figs. 1, 2, 3, 4, and 5. As a result of optic atrophy and degeneration of the retinal ganglia, the power of vision is gradually lost and there is formed a peculiar cherry-red spot in the region of the macula lutea and fovea centralis of each eye. Hearing, as a rule, became hyperacute. In the beginning of the illness there is a general muscular weakness with slight flaccidity or spasticity of the extremities and a diminution or increase in the reflexes. Nutrition is usually good. In the course of the disease, the child loses entirely the power of vision, there is marked spasticity with increase in the reflexes and general or local spasms. It wastes to a skeleton and lies in a helpless condition till death, coming always in the wake of this hopeless disease, finally relieves the little patient of its useless struggle.

The diagnosis is comparatively easy. The history is always suggestive. A healthy, usually breast-fed infant, and thriving both physically and mentally, begins at about the age of a half year to go downward in body and mind without any definite cause. There is a certain peculiar facial characteristic which is only expressive of this disease. A general physical examination will show changes in the neuromuscular system. There may be paresis of the extremities with slight increase in the reflexes or a general spasticity with exaggerated reflexs. There is usually a strong hyperirritability of the nervous system, so that when the child is suddenly touched or moved it starts as if in fright or may have a general convulsion. Nystagmus and strabismus are not infrequent and hyperacusis is almost constant. An ophthalmoscopic examination of the eyes is essential to a proper diagnosis. In every case of infantile amaurotic idiocy there is seen a circular cherry-red spot surrounded by a grayish white halo in the region of the fovea centralis and macula lutea, as shown in Fig. 6. This retinal red spot on a whitish background is so pathognomonic of this disease that its presence makes the diagnosis positive while its absence is strong evidence against such a diagnosis. The course of this disease is in all cases almost uniform and its termination is always fatal.

This infantile amaurotic disease should be distinguished from the juvenile type of amaurotic idiocy. The juvenile type occurs at a later age, is not restricted to the Jewish race, and has not the retinal red spot. The onset is more insidious and the disease is more chronic. The infantile type is illustrated in the following cases.

Case I.—(Fig. 1) V. S. A female infant, 15 months old. The parents are young, healthy Russian Hebrews. No history of syphilis or other infection in the parents. No parental blood relationships. No taint of neuroses or psychoses in either family. The little patient is the first and only child. Pregnancy, birth and lactation were normal. At about five months of age the mother noticed that the child was not developing properly, she also thought that the baby was never just right. On examination there was seen a well developed, well fed, stupid looking baby with the facial characteristics of an amaurotic family idiot. The anterior fontanelle was open, the posterior closed. There was a general superficial glandular enlargement. Had two lower incisor teeth. Examination of the heart, lungs, and abdomen was negative. Vision was impaired and there

Fig. 2.—Case II, H. G., an amaurotic family idiot, 10 months old.

was slight strabismus. The baby was unable to sit unsupported. Wassermann and Von Pirquet tests were negative. An ophthalmoscopic examination revealed the cherry-red spot. The child gradually grew worse and became totally blind. Spasticity became marked and the reflexes much increased. There was great

hyperacuity and hyperirritability with frequent attacks of local or general spasms. No Kernig or Babinsky sign but the Chvostek sign was present. The baby became greatly emaciated and lay in a helpless condition until a bronchopneumonia made an end to her suffering at the age of twenty-three months.

FIG. 3—Case III, R. S., an amaurotic family idiot, 10 months old.

CASE II.—(Fig. 2) H. G. A male infant, 10 months old. The parents are healthy Jewish people. No history of syphilis, alcoholism, or any other chronic ailment. No parental consanguinity. This baby is the third child in the family. The first and second are alive and well. Pregnancy, birth, and lactation were normal. The health and development during the early months of life were noneventful. At the age of about half a year it was noticed that the baby did not hold up the head properly and was not bright enough for his age. Examination showed a well developed foolish looking baby. The weight and measurements were normal for the age. Anterior fontanelle was open. Had six teeth. Examination of the chest and abdomen was negative. There was spasticity of the extremities with exaggerated reflexes. Vision was almost entirely gone. The typical cherry-red spot was present in each eye. Von Pirquet and Wassermann tests were negative. The child was not brought for further examination. By this time he has probably succumbed to this relentless disease.

CASE III.—(Fig. 3) R. S. A female infant, the seventh child of healthy Russian Hebrew parents. First cousins. No history of any chronic illness or psychoses. The child was born at full term, the labor and the breast feeding were normal. Two months before this child was born, her sister, who was the sixth child in the family, died of amaurotic idiocy at the age of twenty-one months. The other children are alive and well. When the baby was only a week or two old the mother noticed that she was very hypersensitive to sound. Between the fourth and seventh month of age she had frequent twitching of the upper eyelids. At the age of eight months the child was unable to raise the head and did not make any effort to sit up. She was dull, listless, and paid no attention to familiar people or objects. At ten months of age, a general physical examination was negative. The anterior fontanelle was open, the posterior closed, cranial sutures closed. There was no nystagmus or strabismus and the child could see fairly well. But an ophthalmoscopic examination already revealed the cherry-red spot in each eye. There was no apparent change in the neuromuscular system. The Wassermann and Von Pirquet tests were negative. At the age of eighteen months there was a marked decline in motor function and a general spasticity with increased reflexes. The face was idiotic, vision almost gone, and hyperacusis was marked. Between the eighteenth and the twenty-third month of age the child grew rapidly worse. She lost a great deal in weight and wasted to a skeleton. The anterior fontanelle was now larger than at ten months of age, the posterior fontanelle opened and the cranial sutures separated, due evidently to an accumulation of fluid in the cranial cavity. There was total blindness and an idiotic expression. The mouth was kept almost locked, general spasticity and episthotonus were marked and the reflexes much exaggerated. No Kernig or Babinsky sign, no ankle clonus, but the Chvostek sign was present. There were frequent attacks of tonic and clonic convulsions and occasionally facial spasms. At twenty-five months of age the child was in a state of extreme atrophy. She lay in a helpless condition with the arms and legs extended, the hands flexed and contracted and the feet markedly extended as I showed in a photographic illustration in the *New York Medical Journal*, November 10, 1917. During the twenty-fifth month of age the unhappy infant died.

CASE IV.—(Fig. 4.) S. G. Is a male baby 17 months old. The father and mother are young, healthy Jews. No history of syphilis, tuberculosis, or any other chronic infection or intoxication. No parental consanguinity. The little patient is the second child; the first died of pneumonia at eight months of age. Pregnancy, birth, lactation, and the development up to the age of seven and a half months were normal. At this age the child was sick for three days with high fever and was in a semicomatose condition. No diagnosis was made by the attending physician. Immediately following this illness, the baby began to lose strength, could not sit up or hold up the head unsupported as it used to do before the illness. The entire disposition of the child was changed; he was dull, indifferent, paid little attention to his surroundings, and did not grasp objects within reach. At eleven months of age, the infant had an attack of convulsions. Now at seventeen months of age the child looks well developed but is dull and listless. There is hardly any vision left. The typical circular cherry-red spot in the macula lutea is present. The anterior fontanelle is open. He has four teeth. The chest and abdomen are negative. There is a general spasticity and increase in the reflexes. A fine tremor in the lower extremities is elicited during reflex excitation. No Kernig or Babinsky sign. No nystagmus or strabismus. Marked hyperacuity and irritability. The weight and measurements are normal for the age.

FIG. 4—Case IV, S.G., an amaurotic family idiot, 17 months old.

CASE V.—(Fig. 5.) S. L. A male infant, eleven months old. He is the first child of young healthy Jewish parents. There is nothing of importance in the parental history. No consanguinity. Pregnancy, birth, and lactation were normal. He was considered a normal child till eight months of age, when it was

noticed that he was not doing well. He was dull and indifferent. Could not hold up the head or sit up. A physician was consulted several times and he thought that the trouble was due to difficult teething. Examination at eleven months showed a well developed baby with a careless facial expression, a blind, aimless look,

FIG. 5—Case V, S.L., an amaurotic family idiot, 11 months old.

and an occasional silly smile. The anterior fontanelle was open, he had four teeth, examination of the heart, lungs and abdomen was negative, there was slight spasticity of the extremities with an increase in the reflexes. The child was almost blind and had the typical cherry-red spot. The measurements were normal and the Wassermann test was negative.

There is no known treatment of any value in this disease. Proper feeding and the best hygenic care should be given. Bromides and warm baths are soothing to the irritable nervous system.

From an observation of these five cases and a few others that have come under my care, some interesting points have presented themselves. All these infantile amaurotic idiots came from parents that were apparently healthy in body and mind and were young or at most of middle age. They all happened to come from about the same social and economic class. People that knew no privation, led a clean life, with clean habits. Pregnancy, birth, and lactation were normal in all cases. They all had the same peculiar character-

FIG. 6—The eye grounds in amaurotic family idiocy. From an original drawing by Waren Tay in "Diseases of the Eye," by Norris and Oliver. (J. B. Lippincott Co., Philadelphia). Note the circular dark spot in the center of a whitish field.

istic amaurotic-idiotic facies. The voice in all infantile amaurotic idiots has a certain vibrating nasal quality, due probably to paresis of the soft palate. In all of them the disease passed through the same cycle of events with almost monotonous uniformity, and eventually all met the same fate.

The etiology of this disease and the reason for its predilection for Jewish children is as obscure now as it was when Waren Tay first described it in 1881. The disease is either congenital or acquired. In favor of its being congenital is the very early onset, the identical course of events, and the same termination in all cases. Such exactness and uniformity in the time of onset, the period of illness, and the pathological and clinical manifestations must evidently be caused in all of them by one and the same biologic dysfunction. But whence does this mysterious illness come? The parents of all of them seemed to be healthy and apparently come from a healthy ancestry, while parental consanguinity was present only in Case III. Still the Mendelian principle may perhaps supply the missing etiology.

Assuming that the disease is acquired, then the infant must be infected at birth or immediately after, and there is an incubation period of six or seven months at which time the disease manifests itself. It is doubtful, whether, as is commonly supposed, the infant is well up to about a half year of age and then almost suddenly begins to degenerate in body and mind without evident cause. In cases I and III it was noticed from very early infancy that the children were not exactly normal in every way. There was at all times some evidence of physical and mental ailments. Case IV suggests the possibility that in every case some acute illness may be the cause of the breakdown of the nervous system which was at no time equal to the task imposed upon it by the wear and tear of life. But the nature of this supposed nerve infection or intoxication is unknown. It may not be impossible that the much wanted etiology will ultimately be found in some abnormal action or reaction in the endocrine group which has a profound influence over the general metabolism and the life history of the nerve cells. But, at present, there is no evidence of an endocrine pathology in infantile amaurotic idiocy. It must therefore be assumed that the cause of this disease lies in an abnormal physicochemical structure of the nerve cells which limits the span of their life to a little over three-score and ten weeks.

222 EAST BROADWAY.

ON THE DESIRABILITY OF INSTITUTING A SPECIAL MEDICAL BOARD WHICH SHOULD CORRESPOND TO THE PATENT OFFICE:

THE FUNCTION OF THIS MEDICAL BOARD BEING TO ESTABLISH AND PROTECT THE PRIORITY OF IDEAS RELATING TO MEDICAL SUBJECTS.*

BY A. L. SORESI, M.D.,
NEW YORK.

IF the ethical principle accepted by all reputable physicians that they shall not profit directly by any invention that relates to medical science, is the proof that the medical profession stands on such a high plane as perhaps no other profession does, this does not mean that the men who have—or have

*Read before the Historical Section of the Academy of Medicine, Nov. 22, 1919.

had—the original ideas that make medicine a really progressive science, should not be given full credit for their original pioneer work. Some one might object that pioneer work is recognized and given full credit nowadays and might bring forward thousands of instances to show that his assertion is correct. This does not mean that full recognition is an actual fact in all cases, and I might add that the cases where the originator of something really new fails to receive full credit are more numerous than the cases where full credit is given.

Let me give you an instance that illustrates my point: Cystoscopy is nowadays one of the most valuable means of diagnosis and direct treatment of numerous diseases. To whom are we indebted for such a wonderful means as cystoscopy being given to the medical profession? Obviously, to the man who first devised what would be called the basic instrument that made cystoscopy possible and whose fundamental ideas are embodied in all the more perfected modern cystoscopes. Well, what credit is Nitze given for his really original and fundamental work? In some textbooks it is mentioned that Nitze applied a lamp at the end of the instrument, but the modern cystoscopes are called simply Doctor A's, Doctor B's, Doctor C's, Doctor D's, etc., cystoscope; no mention is made of Nitze's instrument, notwithstanding the incontrovertible fact, that each cystoscope is nothing but a modification of the original Nitze's cystoscope. Don't you think it would be only fair to associate the name of Nitze with the name of the man who made the modification and call the improved instrument cystoscope Nitze's and Doctor A's, Doctor B's, Doctor C's, etc.? This combination of names was not objected to on patriotic grounds—Nitze being a German—but because of the deplorable tendency to forget what is due to real pioneers, if their names are not of actual value in increasing the reputation of the man who happens to modify in some details the work of the originator. And without any idea of passing personal remarks, but only in order to protest against a deplorable tendency and prove my assertion, I recall a fact that you all know. There was in this city a doctor who worked many years and spent considerable money and time in improving the cystoscope, Dr. Brown; well, after his death we saw advertised an improved cystoscope called Brown's and B's; then the cystoscope was still improved, until perhaps it is the best on the market, but the name Brown was dropped. Who remembers poor old Brown and his hard work?

The medical man who does original work spends his energies, practically always his money, and often sacrifices his health; he does not get the applause of the crowd, his name is unknown to the crowd; people will bless the physician who helps them or their dear ones, without knowing that the help they receive is the result of the patient, often tedious and dangerous, work of a man—living perhaps in another continent—who spent his lifetime studying, in order to solve some difficult medical problem. If any one of us lights an electric lamp the thought will go, not to the electrician who installed the lamp, but to Edison, to Volta, to Galvani; if a child is dying of diphtheria, the physician injects some antitoxin, the child is saved, but the thoughts and thanks of the mother do not go to Roux or Behring, but to the physician who actually does the very simple injection of the live-saving antitoxin.

The physician who does original work not only does not derive any money or even fame and glory in most cases, but often, and when his discoveries are most important, is compelled to fight in order to see his sound ideas accepted, when he is lucky; in most cases he will have to stand humiliation, to be considered a fool or a crank, until he is old and worn out, or decidedly dead. This has been true in past centuries, when pioneers in research work were excommunicated or more simply hanged or burned, and is true nowadays, when too often we kill a man's ambition by lack of recognition of his work. I can give you a most striking instance illustrating my assertion, by recalling to your attention the fact that therapeutic pneumothorax was advised and practiced by Forlanini over thirty years ago, yet, notwithstanding his splendid work done in the clinics of the Universities of Torino and Pavia before physicians and students, and his ability as a clinician, therapeutic pneumothorax was not accepted until recent years; some have even tried to take away from Forlanini—great modest man that he was—the full credit for his important pioneer work. Forlanini was perhaps to be blamed for being an old-fashioned scientific man, who did not have the ability of some modern scientific men, who know how to use the lay press in order to gain fame and diffuse their new medical discoveries among the laity and the profession. May I ask, if Forlanini, instead of being professor of clinical medicine in two of the largest medical colleges, had been a modest physician in a small town, would not someone else have taken away from him the credit for having given the medical profession such a valuable means as therapeutic pneumothorax?

Someone might answer that the priority of any medical idea is guaranteed by the date of publication in a medical journal. I feel sure that anyone having the least familiarity with medical literature knows that the date of publication does not mean much, and I shall give you a most striking illustration of how much it does actually mean. While visiting different clinics abroad after the armistice, I happened to see a surgeon who, having completed a difficult suture deep in the abdomen, had accidentally torn one end of the thread and was in a rather bad plight, being unable to tie any knot. I suggested that he tie the knot with the aid of forceps and he thanked me very sincerely and warmly, saying, "I had not thought of the Dr. G's knot." No one can imagine my surprise, because the so-called "Dr. G's knot" was described by myself in *The American Journal of Surgery* in March, 1911, and I had personally taught Dr. G. how to make it in 1915, while he was taking a course in my surgical institute. Well, this gentleman, Dr. G., published in 1918, in two most important and widely circulated surgical journals, *The Annals of Surgery* and *Surgery, Gynecology and Obstetrics*—after having read a special paper on the subject before two different surgical societies—two papers describing a new method of tying a surgical knot. After having mentioned my name, my paper, and the fact that I used forceps to tie knots, he also had the nerve to state: "I find nothing in the literature describing this method." You can see for your-

selves from the original articles that I present to you and a letter received by Dr. G., that he did not make a simple mistake of omission, but intentionally presented as his own a procedure that he had learned from me and that he knew was not originated by himself. I mention this case, not to claim any especial priority about tying a knot—the matter is of small importance and the man concerned is smaller still—but to prove that medical publications do not really protect the originality of any idea, so that the originator may be put in a very unpleasant position, as happened to me in the case referred to, when, not having any reprint with me, I could not prove my case, and might have left a bad impression—absolutely unjustified—in the minds of the surgeon and his assistants.

If medical publications do not protect originators in a case as simple and plain as the one referred to, what will happen when the matter is rather complicated, such as new ideas about treatments, pathogenesis, etc.? And allow me to ask you: What protection has a man doing original work when he starts to study a subject that requires laboratory experiments and clinical investigations that must be carried on for a long period of time? I could refer to several personal instances in which original work which I had started was published by other men before I had an opportunity to do so, pressed as I was by the enormous amount of work that I was doing, but I shall not take up too much of your valuable time. It is sufficient to state these facts:

The man who does original work has no means of protecting his ideas, and unfortunately there are men in our profession who are unscrupulous and try to take away the credit of anything new from the real originator. It is absolutely right that no medical ideas should be exploited for financial gain or through the lay press, because we all want to keep the science and art of medicine on a plane where speculators in human ills have no place; *but some simple and efficient means of protection should be offered to anyone doing original work in medicine. This protection is not only the duty of the medical profession towards the ones who sacrifice themselves in doing original work, but it is indispensable in order to help the progress of medicine.* In fact when a man starts to do original work nowadays, he either has to do it in secret or run the chance of somebody taking away from him the credit for his ideas. If he works in secret many elements that might help him will not be made use of, and not only would progress be slow, but many good works would not be carried through on account of the impossibility of any one man being able to solve all the problems that will present themselves during the study of any medical subject; if he does not do his work in secret, an injustice is done him, because his ideas are not protected.

Allow me to state that the originator of any new idea might have that idea in his mind very clearly from the beginning, or the idea might be rather hazy and require a great deal of thought in order to make it clear to the originator himself; then comes the process of thinking how to make the idea practical and translate it into words and facts; at this moment the originator can state what he is aiming it and can start on actual work. The original idea might at first seem to concern only a rather small matter, then its importance broadens until, at times, it might become the basic idea from which many others will originate. The genius is one who starts some new basic idea that will allow other intelligent men to do some progressive work. Columbus was a genius, because he conceived the basic idea of the existence of a new continent, the other discoverers who came after him only developed the original basic idea of Columbus, and if an enormous number of men have contributed to make America the most progressive country in the world, each one should be given the credit he deserves for his contribution; no one, however, forgets the one that made such a wonderful country possible, Columbus.

The same acknowledgment should be made in things pertaining to medical science. We have the giants like Pasteur, and we have big and less big men, each contributing to the progress of medicine according to the amount of talent with which Nature has endowed him; all, from the giant to the smallest man must receive full recognition for their contributions toward the progress of medicine. The smaller men must not try to steal any of the credit that is due the bigger men. The small man has to understand that what counts is the basic idea, not the details that hundreds of other men, either today, or tomorrow, will certainly improve; and if the small man does not understand that he has to pay his respects to men of broader minds, who have done real pioneer work, the medical profession —which as a whole is the most just and fair association of men existing today—must find a means of making him understand that fairness and honesty are the qualities that must always distinguish the medical man, and that we are so proud to possess such qualities that we do not want anyone among us who does not feel that fairness and honesty must be inborn in the physician and the most essential of his qualifications. I say this much because we see sometimes, indeed too often, men who have contributed small details toward perfecting some valuable contribution to medical science, speak with a kind of scorn of the men who originated the very thing to the perfection of which they have contributed some detail—perhaps of no great importance—speaking and acting and pretending recognition, as if they were the inventors of the whole thing. To keep up the illustration given before: What right have the different men to call a certain cystoscope, Dr. A's, Dr. B's, Dr. C's, when in reality Dr. A, Dr. B, Dr. C, and Dr. D have only modified details, and what right have they to the advantages that come from the supposed invention of a new instrument, as important as the cystoscope, that gives them great prestige among laymen and perhaps also among physicians?

I remember a very conceited surgeon showing me an apparatus for traction on fractured bones and telling me that it was absolutely new and original; I made the remark that after all it was nothing but a modification of the old Codivilla's nail—as in reality it was. But if I had not known Codivilla personally, I would not have formed a very good opinion of him from what this surgeon had to say about him. Poor Codivilla, he had the nerve and audacity to present something new about twenty years before this great small surgeon invented the same thing.

I shall not insist any further, because I do believe that all of you are convinced that nowadays the medical profession does not offer any protection to the ones who intend to do original work, and that such protection should be given, because it is a moral duty of the medical profession toward the ones who help the progress of medical science. The necessary protection can easily be given and the patent office offers us a plan that we can imitate and adapt to the peculiar conditions of medical science. The patent office does not grant a patent that infringes the claims of one already granted, or for which an application has been previously filed; this means that the priority of any claim is awarded to the person who first made the application for such recognition, whether a final patent has already been granted or not.

Following these general outlines I propose the institution of an international board that would have the authority and power to pass on the priority of ideas relating to medical subjects. Anyone, physician or layman, having or thinking to have an original idea relating to any medical subject, communicates such ideas, as clearly as possible, with the help of sketches, models, diagrams, etc., when this is deemed desirable, to the secretary of the board, formally filing an application for a claim of priority.

The secretary shall record the date of the presentation, when the application is brought directly to him, or the date of mailing, as marked by the official post-office stamp, when the application is sent by mail; the date on record will be the one on which the claims of priority will be based. The secretary and his staff will study the application, when the claim to priority can be easily established or rejected, and a decision will be reached as rapidly as possible; when the matter is rather complicated, members of the board specially competent will be consulted before passing judgment on the application; when the matter is exceedingly important and complicated, the decision could be left to special meetings of the board, to which the applicant and the medical profession should be invited to be present and discuss the matter. The decisions reached by the board should be final, and should be accepted by the profession when referring to authors who have done original work.

The board should be international with national branches in all civilized countries, and should furnish any information regarding medical subjects upon the payment of a small fee, so that anyone thinking he has an original idea can at a small cost obtain all the information necessary about the subject in which he is interested. By this arrangement the board would not be burdened with applications for priority of ideas which evidently are not new.

Applications for priority of ideas that are not developed within a certain time—to be determined later by the board—should be considered void, and as not made. The board should be international in order to have the necessary authority to carry on its work and take care of any new ideas that may be developed in any country, so that the possible abuse now existing that a man might publish something new in a small journal, published in an unimportant country, the language of which is not universally understood, therefore obtaining little or no notice at all; and then see someone else take up the same thing and publish it as his own and be given credit for it, would not be possible; for the board would offer complete protection to the big as well as to the small men, to the big and to the small countries alike, and would be completely fair.

I propose that any person, either physician or layman, can apply for a claim of priority of any idea relating to medical subjects. I do this for two reasons: first, because men who are not physicians might and have helped and actually do help the progress of medical science, and they have a right not only to the gratitude of the profession, but also to receive the credit for their valuable contributions; and I may recall to your attention that to a chemist, Pasteur, we owe the most valuable personal contribution to the progress of medical science; to a singer, Garcia, we owe the laryngoscope, to prove that my inclusion of laymen constitutes fair play and is justified.

The second reason is that chemists, manufacturers of surgical instruments and others, do contribute to the grogress of medical science, and it is right to give them credit for their good work, not only because this is fair, but because it would also stop a practice that is really shameful, and I shall explain myself in very plain words: We see advertised, instrument Dr. So-and-So, electric outfit Dr. So-and-So, preparation Dr. So-and-So. Well, in a great percentage of these cases the doctor whose name is associated with the instrument, the operating table, the electric outfit, preparation, and what not, had as much to do with the invention, or at times even, with the perfection of even small details of the instrument, operating-table, electric outfit, preparation, etc., as any inhabitant of the moon, if there be any such. What happens in these cases is this: The manufacturer has devised or perfected a surgical instrument, an operating-table, an electric outfit, preparation, etc., the original idea of which might be due to somebody else; the market value of these products depends, however, on the label attached to them, as the labels on bottles of wine—during the happy times when there were bottles of wine—made the market value of champagne; the manufacturer therefore needs a good label, and he gets it by attaching to the apparatus the name of a more or less famous medical man, who not being the champagne itself, is satisfied with being the label.

The immorality of such practice does not need to be emphasized, and I am sure that you will all agree that it should be stopped; the name of a physician should not be attached to any commercial invention, unless the physician himself is the real inventor; any physician giving his name to any commercial invention, when he is not the real inventor should be disciplined and made to realize that if he has no self-respect he must respect his qualification as a physician and not drag it down as a label for commercial purposes. The constitution of such a board as I have advised would immediately put a stop to such a practice, because the manufacturer would inform the board of his intention of making a new apparatus, and when the apparatus is finished and put on the market, he

could not have a more or less famous medical man give his name to it, because it would be recorded under the name of the manufacturer. Some one may object that the manufacturer could record the invention under the name of a physician; this might happen, but it is not so likely to occur as would appear, because the gentleman who gives his name to something to the making of which he has not contributed, gives it only to the finished product. There is then no risk of failure, and he gets a valuable advertisement only in exchange for respectability; and when you consider how often a valuable surgical instrument has made the reputation of a surgeon, you will realize that there are —unfortunately—men who are ready to exchange self-respect for the good sound dollars that go with reputation, no matter how acquired. On the other hand, when the physician himself is the inventor he will file the application for priority, as he would file the application for any other idea, so that full credit should come to him.

The next and very important point is the financial side of the proposition. I do believe that there are many ways of solving it. The Carnegie Institution, which publishes the *Index Medicus*, or the American Medical Association could be interested in the matter; then there would be some revenue from the fees paid by persons applying for information and for recognition of claims; the board could even take patents on inventions that can be exploited commercially and receive a royalty on the same from manufacturers. There could be no objection to this practice because it would not give rise to any commercialism, as the inventors or the members of the board would reap no personal benefit or monetary gain. The fund thus collected might be used, in addition to defraying the current expenses, to help develop ideas that require a very large outlay of money. This point is especially important, because we must not forget that often the most intelligent men are also the poorest.

If the objection is made that permitting the board to patent ideas which relate to medical subjects and make a profit on them, would result in physicians and patients having in the end to pay for such profit, I shall answer that, if physicians and patients do really pay such a contribution, this contribution will be so small and the benefit derived from helping medical progress so great, that the gain will be wholly theirs, because the progress aimed at will benefit them and save them larger expenditures of money, on account of disease which can be either prevented or treated more scientifically, if medical progress is favored. I am also of the opinion that after the board has been established, it would not be difficult to obtain part of the funds necessary for its activities through contributions from governments, institutions, and individuals.

I move, therefore, that the Chairman of the Section of Historical Medicine appoint a temporary board, that will study the practical details that are necessary to start the institution of an international board, the function of which shall be to establish and protect the priority of ideas relating to medical subjects.

ANESTHESIA IN CEREBRAL AND SPINAL SURGERY.

By ANTHONY M. PALERMO, M.D.,

NEW YORK.

ASSISTANT SURGEON, NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL.

In brain and spinal surgery, the anesthetic is most important; the surgeons in this field show their appreciation of this by employing one experienced in this line of work, and consider him as important as their trained assistants.

The method of administration for these patients is markedly different than that used in general surgery.

Ether-oxygen is most frequently used. Ether, properly given, is a stimulant—the only anesthetic that has a stimulating action upon the circulatory, respiratory, and nervous systems, and like other stimulating drugs, if not properly used, it depresses these systems.

Chloroform acts directly upon the heart muscle, depressing that organ and at times causing death; there is the added danger due to the locking up of a very toxic agent within the lungs, to be absorbed and to act still further upon the already poisoned and embarrassed heart.

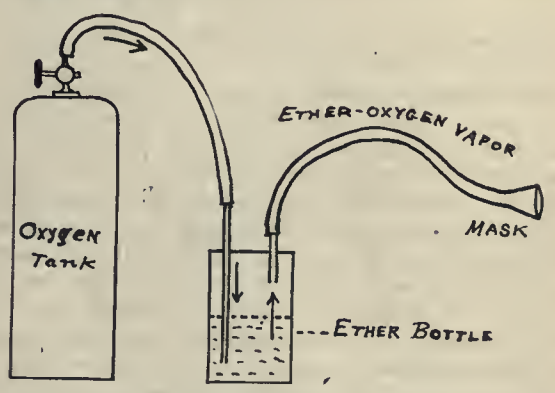

Fig. 1.—Diagram showing the method of obtaining the ether-oxygen mixture.

The method of nitrous oxide: oxygen is rarely used; I will say never. The anesthesia is too superficial and uncertain. The inhaler is in the way of the operator and assistants, and the anesthetist is handicapped by being unable to control his patient without disturbing the operative field. The closed method by which nitrous oxide and oxygen are given in some cases causes venous congestion of the lungs, brain, and other organs of the body, which is undesirable in brain surgery; the blood pressure is markedly raised.

Ethyl chloride and numerous other agents employed for general anesthesia are not to be considered in this special branch of surgery.

Ether seems to fill the vacant space between nitrous oxide on one side and chloroform on the other, in that it is more efficient and reliable than the former and much safer than the later.

Of the many complicated automatic apparatuses, I have ultimately come to use just the simple oxygen tank, on the side of which hangs a bottle containing ether—the anesthetic I use constantly. In this way the oxygen becomes saturated with ether vapor and thence it is carried to the lungs as such through a

FIG. 2.—Showing the operation performed under ether-oxygen anesthesia.

tube running from the bottle to the mask, as illustrated by the accompanying diagram (Fig. 1.).

The administration of the anesthetic to these patients is made more difficult because the administrator must remain at the foot of the table so that he may not interfere with the work of the surgeon and his assistants. The patient is draped and is entirely covered so that little opportunity is afforded the anesthetist to observe the patient; the respiration, pulse, and color of the blood are his only signs. The quantity of either given is dependent upon the amount of oxygen going through the ether bottle—the more oxygen, the more ether vapor.

Before the administration of ether, if the patients are asked to breathe rapidly and deeply for a few minutes, there is hyperoxygenation of the blood which seems to lessen and obtund the sensibility; under no circumstance should a patient be forced to take an anesthetic—this is as true for children as for adult patients. Only management is necessary to secure the cooperation of even a very young child; the anesthetist may even himself breath through the cone and let the patient play with it. In adults there should be some practice in deep breathing deliberately before using the anesthetic with the object of accustoming the respiratory mechanism to take deep breaths by habit even when not entirely under control of the will—and the patient should have the suggestion of this effect frequently repeated in his ear as he "goes under" the anesthetic. The occupation of attention necessary for deep breathing during the taking of the anesthetic lessens the concentration of the mind on the sensations and actually lessens the discomfort. Besides, deep breathing distributes the anesthetic over the lungs, leads to its absorption more rapidly, and makes the irritation of the anesthetic less by diffusing it over a larger surface. On the contrary, short rapid breaths lead to an intensity of the irritation and a much slower absorption.

The anesthetic is started with pure ether, using the Yankauer mask, and after the patient is fairly under its influence the operative area and the patient are draped; the anesthetist now retires to the foot of the table and the ether-oxygen tank is now connected. The patient is kept very slightly under—and in children, usually crying, but relaxed. He is kept this way until the dura is opened—when the narcosis is increased. In brain surgery, from the time the bone is removed (permitting the bulging of the dura), unless the depth of the anesthesia is increased when the dura is incised, and if there is much loss of cerebrospinal fluid or a marked bulging of the brain itself, some reflex condition results, such as a change in respiration, coughing, swallowing, et cetera; but this does not occur in the same degree, or as often, if the patient is well anesthetized at this time. As soon as the operator begins to suture the incision, the anesthesia should be lessened and then discontinued when the temporal fascia is sutured. In this manner, the patient requires very little ether and is entirely out of the anesthesia before the operation is completed—and only mild or no signs of shock are apparent. Rarely does the patient complain of having suffered from pain during the operation.

To date, 250 patients have been anesthetized in this manner and not a single death or complication has occurred which could be attributed to the anesthesia; of this number:

158 were subtemporal decompressions; 12, suboccipital decompressions; 16, Gasserian ganglion operations; 14, laminectomies. The accompanying illustration (Fig. 2) shows (1) the anesthetist at the foot of table; (2) the oxygen tank with bottle of ether hanging on side; (3) the patient completely out of sight. I have never tried intracranial, intravenous, or rectal anesthesia as I think it is unnecessary to resort to more difficult and dangerous procedures in view of the results obtained with the ether-oxygen method as described above.

408 WEST 145TH STREET.

WINE IN FRANÇOIS RABELAIS' DAY.

By DOUGLASS W. MONTGOMERY, M.D.,

SAN FRANCISCO, CALIF.

THE mental attitude toward wine then and now are two totally different things. Then wine was intimately associated with theology, and with a thousand social customs almost equally sacred. It was considered both theologically and physiologically to be one of the two chief sources of blood, and the fermentation of the grape was regarded as the type for the processes of digestion. The stimulation produced by it, now classified as the first stage of its poisonous action, was then thought necessary to evoke the manifestations of genius.

It would be difficult now to arouse a religious fervor over a formula like C_2H_5OH, or to impress the public with the preeminent food value of a little ethyl hydroxide, some volatile ethers, some flavors, sugar, and a little coloring matter assembled together in watery solution. Furthermore, the physiologist, who would draw his entire ideas of alimentary digestion from the fermentation in a wine vat, would get little attention, and the epicure and social enthusiast is rather stumped on reflecting that the subject of his enthusiasm is the refuse of a microorganism, with life processes essentially similar to those of his own.

However, we have so many facts to sneer with nowadays that we must be a little careful in our sneering. In many situations wine (and its fellow drinks) is still "a good creature," and we should be much at a loss without it.

Rabelais was so fond of wine and of eating and of their attendant joyousness and goodfellowship, that he was scarcely dead before the legend arose that he was a brutalized drunkard and glutton. And yet he was as far removed from being a drunkard as he was from being a teetolar. He might, occasionally, as he has said, get the registers of his brain a bit confused by partaking too freely of new wine, but few have given more vivid descriptions of the brutalizing effects of over-indulgence in either food or drink.

He had several pet names for his favorite drink, such as purée de Septembre, a name for must or new wine, which was pressed out in September, the month of the ripening of the grapes. Another was "Eau bénite de Cave," holy water of the cellar, a characteristic monastical designation, quite in accord with Rabelais' status as a monk, and, according to Abel Lefranc, probably original with him.[1]

Another pleasant synonym was vine-tree syrup, with which the breath of the priest, who helped Prince Gargantua to dispatch his matins, was well fortified against the raw morning air.[2]

Piot, from the Latin *potus*, was another favorite name for that nectaric, delicious, precious, celestial, joyous, and deific liquor called wine. Janotus de Bragmardo employed this term in his well-known harangue, and said that if we lost it we should also lose sense and law.[3] Was this in the nature of a prophecy? It would seem so, for since losing our wine we notice a notable crop of senseless and lawless socialistic theories spread abroad in the land. It would appear as if men, losing their solace, become as cantankerous, vicious, and wrong-headed as old mares, and that when they assemble they either try to be zealously edified, or, like the parlor Bolsheviki, they think up some delivish scheme against their neighbors. "A cup o' kindness" might change the whole social atmosphere.

The Cherished Vintage.—It is not every year that produces good wine either in plenteousness or in flavor, and an especially good vintage was so lovingly regarded, and was such a notable event, that it was used as a chronological point of departure. It was the year of the good vintage, "Ce fut l'an de la bonne vinée," was an even better introduction to a story than "Once upon a time."

And the wine of that year was bottled with especial care, and kept for great occasions, and when it was drunk the stories and the old friends of that year were brought to mind. Warren Gregory of the Belgian Relief, in speaking, one evening, of the irrepressible Belgians, said that an old butler gave him a glass of wine, which he said he had helped to bottle sixty-five years before. He also added that there would be one big time when the Germans would be driven out of Belgium, for many were saving up, in the most recondite places, the wine for the occasion. I have no doubt that that "Big Time" was pulled off according to schedule.

The Time for Drinking Wine.—The time of day to drink wine was seriously regarded. In reading Rabelais, however, one would think that when anyone had a thirst it was seized upon as a fitting time to drink.

In the prologue to the fourth book he says that at prime he drank white wine, also at *tierce*, *sext*, and *nones*. At vespers and at compline he drank claret. This meant that he drank the whole day through, from early morning until he went to bed, for prime was 6 o'clock in the morning, or sunrise at the equinox, while *tierce*, *sext*, and *nones* were three of the quarterly divisions of the old Roman day, carried over into the Church of Rome. And vespers are the *vesperæ* or evening hours, while compline, Latin, *completæ*, is the last service of the day, completing the service of the canonical hours, and it also designates the hour of that service. The poor tired sisters occasionally forget the compline, and then they have to drag themselves out of their nice warm beds in order to close the day properly.

Wine Before Breakfast.—I well remember the shock I received one time when crossing the ocean on a North German Lloyd steamer. A young Teuton on board began the day, every day, by drinking Munich beer. He had resided for some years in a remote part of Mexico, far removed from that delicious drink, and the morning seemed long to him in awaiting the opening of the bar.

Friar John is another instance of an early drinker, but there were extenuating circumstances. Friar John cried out "Cool wine, cool wine, Gymnaste, my friend!" No wonder he cried out for a cool, fresh drink, for the worthy monk had just come in from one of the most strenuous single-handed combats ever recorded in history, and furthermore, it was a hot September morning, just after sunrise, and he brought with him five pilgrims, and a captain as prisoner. In fact, he was returning from being prisoner himself, which was no light matter. We must also take into consideration that wine was then the only exhilarating drink, as tea and coffee had not yet been introduced.

Taking an alcoholic drink, as a cocktail, as a preparative initium to a meal, is an old custom, and we find that on a sultry evening Gargantua went out into the garden, gathered some lettuce, washed it in a cool running fountain, and after eating it, and so, in a certain measure, assuaging his thirst, he extinguished the latter completely by taking a great draught of wine.[4]

At other times this would be turned about, and salty foods would be partaken of in order the better to relish the wine.[5] And still, at other times, at the commencement of a repast, there would be read some pleasant history of ancient prowess, while they were sipping their wine.[6]

When drinking to one another in Rabelais' time they had a curious expression for "flowing bowl," or, as Sir Walter Scott would say, "a cup so filled that the wine sparkled on the brim;" it was "verre pleurant," literally the weeping glass.[7]

Wine in Elderly Life.—Friar John taunted Panurge unmercifully about the signs of old age which were beginning to show. Panurge admitted that there were indications of age present, but begged him to impart this information to no one, that it might remain a secret between themselves. He admitted, however, that there was one sign he himself had noted. He said that he found wine better and more to his taste than ever, and that more than ever he feared lest he should happen on bad wine.[8]

As a matter of fact elderly people are exquisitely appreciative of the glow and the delicate suave taste of good wine, while sensitiveness to the cruder sorts of wine, or to any excess, becomes more marked as life advances. It shows itself in many ways as an exacerbation of an indigestion, an irritability of the bladder, a quicker flushing of the face, a lighting up of an eczema, an irritability of the tongue and other mucous membranes, a herpes, twinges of the muscles and joints, and a sharpening of the temper.

As the great Scotch Rabelais put it:[9]

When once life's day draws near the gloamin'
Then fareweel vacant, careless roamin',
An' fareweel cheerful tankards foamin',
An' social noise.

Not infrequently one becomes more sensitive to beer than to wine, and, in fact, whiskey is less liable to give trouble than either of them. It is a far simpler drink. It is, to a great extent, the complexity of the other two that works the mischief.

Wine in Surgery.—The narrative of the death of Epistemon in the battle with the giants, when his head was cut off, the replacement of his head, and his restoration to life by Panurge, and the account Epistemon gives of his sojourn in hell, in the intervening time when his soul was absent from his body, is one of the most interesting chapters in Rabelais.

After the battle Epistemon was missing, and Pantagruel was saddened to the point of wishing to commit suicide. When the body was found, Panurge recognized that it was still warm, and taking the head, which had been completely severed from the body, held it safely and warmly, and away from the wind, while the body was being carried to the place where they had feasted the night before. Then he cleaned off the neck and head with white wine. He then adjusted the head on the body with great care, and secured it in place with fifteen or sixteen stitches, and smeared the wound with a resuscitative ointment.

Presently Epistemon began to breathe, then opened his eyes, then yawned, then sneezed, after which he passed some flatus. Upon hearing this Panurge gave it as his opinion that the patient was entirely restored, and gave him a glass of white wine with a piece of sugared toast. In this way Epistemon was cleverly healed, excepting that he was hoarse and suffered from a dry cough for more than three weeks, the only remedy for which was copious drinking.[10]

Besides this use as a surgical dressing, wine was also employed for washing the hands. It is related that Prince Gargantua muttered a number of graces, washed his hands with cooled wine, cleaned his teeth on a pigs' knuckle, and chatted merrily with his companions.[11]

The uses of wine, especially in surgery, are historically very interesting, as in the Middle Ages they were extensively employed. There is still a camphor wine in the German pharmacopœia, originally from the French, and composed of: Camphor, 1 part; 90 per cent. alcohol, 1 part. Dissolve and add: mucilage acacia, 3 parts; white wine, 45 parts.

In the Napoleonic period the attention of the medical profession was attracted almost entirely to pathological anatomy—the dead-house held the center of the field. The science of surgery advanced rapidly, and as it advanced the practice of surgery became worse and worse. It is said that it never was more murderous than in 1870, just at the dawn of its greatest advance. The wines, so freely used in the Middle Ages, had been almost entirely replaced by fatty dressings, ointments, and this most regrettable change contributed its share to the horrors of the Franco-Prussian war. I personally knew surgeons, who, in operating in particularly severe cases, or on gala occasions, would put on gowns stiff with blood and grime, which they had worn at Sadowa (1866), or on the battlefields of France (1870). In scientific attainments these men were far ahead of their successors, the extent of whose knowledge is often limited to maintaining a faultlessly sterile operating field, which, by the way, is no mean achievement.

In the Middle Ages wine was intimately associated with the most sacred religious feelings, and with the most intimate conviviality, both of the community and of the family.

In religion, in social life, and in family life, the drinking of wine was surrounded with most elaborate and punctilious ceremonies. The feelings aroused in regard to partaking of it as a religious ceremony were so intense as to give rise to great wars, causing untold misery and destruction. It was supposed to be both health-giving and life-giving, and was regarded as the analogue of the blood, which was thought to be the seat of the soul. It and bread, indeed, were held to be the substances out of which blood was formed.

Certainly the world does change. It changes so rapidly that the father and son live in two different worlds, each largely incomprehensible to the other. The change of ideas in regard to wine is one of the strangest of these mutations. In all this may be seen one phase of the eternal, always beginning,

never ending quarrel between forms of government; between one generation and the next succeeding to it, and between the ancients and the moderns.

INFLUENZA.

A CONFIRMATORY REPORT UPON THE ABORTIVE ACTION OF QUININE DIHYDROCHLORIDE.

BY WATERS F. BURROWS, M.D.,

AND

ELLIOTT C. BURROWS, M.D.

NEW YORK.

SINCE our preliminary report upon the specific treatment of influenza with quinine dihydrochloride (MEDICAL RECORD, Dec. 21, 1918), a large number of cases have been injected. This salt of quinine was selected because it was easily obtainable in ampoules and but slightly irritating. In every case injected a rapid and uncomplicated recovery has resulted, excluding in this series only those which had developed marked pneumonic signs, in which latter instances, with but one exception, there had evidently been a prodromal stage during which the injection should have been made.

Recalling that but one injection is required to cause the disappearance of the influenza symptoms it seems evident that the treatment is specific to the same degree that antitoxin, used early, is a specific for diphtheria. However, it is probable that the quinine solution acts by increasing the body defenses rather than through neutralization of a toxin. A later communication will deal with this phase of the problem.

The treatment is equally effective at all ages. The youngest injected was four years, the oldest sixty-three. The injections have been made on the first to the sixth day of the disease and also in cases where definite pneumonia existed. The absence of a specific action upon the secondary pneumonia emphasizes the importance of early injection.

Influenza cases with temperature ranging from 101° to 106° with a pulse rate up to 120, with headache and general prostration, have responded almost immediately. Within a short time the headache and general pains disappear, the facies improves, the tongue becomes moist, the temperature and pulse rate drop, and the sense of foreboding present in the most severe cases is lost. Without other medication the cough is lessened, the temperature may drop from 105° to 101° within a two-hour interval, and rarely rises again above 101.°

We do not wait to see if the disease will control itself. The earlier the injection is made the better, and to do otherwise is only to run a risk. It is certainly advisable to make the injection on or before the third day of the average case while the pulse rate is around 100 and the respirations still under 26.

We use a 10 per cent. solution of quinine dihydrochloride. For the adult the dose is 15 to 22 grains given but once and at one time. At least ⅓, often ½, and occasionally the entire dosage is given intravenously. The remainder is injected into the biceps muscles. For young children 7 to 10 grains is the dose. There may be a general tingling sensation and warmth during the injection; sometimes a slight chilly feeling, a transitory pallor if given too rapidly, or nausea.

In conclusion we may state the further course of the uncomplicated influenza case which has received one injection. Within a very short time the entire picture is changed from one of evident illness to one of convalescence. The following day the temperature is about 100° and the patient is well about forty-eight hours following the injection. The irritating cough, if present, may persist for some time and the appetite may but slowly return.

17 EAST THIRTY-EIGHTH STREET.

Medicolegal Notes.

Payment of Assistant Who Administers Anesthetic.—The North Dakota Supreme Court holds that in surgery the proper administration of an anesthetic is an essential part of the operation, for which a surgeon is commonly paid an adequate fee, which includes the minor fee of an assistant. When he employs an assistant the presumption is that he agrees to pay him, unless the contrary appears from express words or conditions. Chief Justice Christianson dissented, being of opinion that the law does not imply any promise on the part of an attending physician to pay the doctor administering the anesthetic at operations. He quoted Garrey v. Stadler, 67 Wis., 512, 516, 30 N. W. 787, 789, as follows: "We think we are justified in assuming that it is quite exceptional for the members of that [the medical] profession to undertake the treatment of their patients on special contracts by which they are to be paid a sum in gross, and by which they bind themselves personally with their patients to pay for any needed assistance in the proper treatment of the case."—Semple v. Kings (N. Dak.), 172 N. W. 817.

Expert Testimony as to Permanency of Injuries.—In a personal injury action objection was made to the admission of opinion evidence of a doctor as to the permanency of the plaintiff's injuries, and that he would never again be able to pursue his occupation of coal miner. The court held the objection was without merit. Proper elements of damages in such cases are the nature of the injuries, and whether permanent or only temporary. Who is better qualified to speak on this subject than an attending physician and surgeon? That such evidence of a medical expert based on actual knowledge of the facts or facts proven by others is admissible is supported by the great weight of authority.—Barna v. Gleason Coal & Coke Co., West Virginia Supreme Court of Appeals, 98 S. E. 158.

Privileged Communications in Criminal Cases.—Under the Washington statute providing that a regular physician or surgeon shall not, without the consent of his patient, be examined in a civil action as to any information acquired in attending such patient, which was necessary to enable him to prescribe or act for the patient, and the statute declaring that the rules of evidence in civil actions, so far as practicable, shall be applied to criminal prosecutions, the Washington Supreme Court holds that a physician cannot, in a criminal case, testify over objection of the accused as to any information acquired in attending him as a patient. The privilege of a defendant accorded by these statutes to prevent a physician from testifying was held not waived by the defendant's voluntary disclosures to others outside of the court.—State v. Miller (Wash.) 178 Pac. 459.

MEDICAL RECORD.

New York, February 7, 1920.

IS THERE AN INFLUENZA CYCLE?

A RECENT Bulletin of the Census Bureau calls attention to the fulfilment of a prediction made by Dr. John Brownlee in *The Lancet* of November 8, 1919. After a careful study of the records of the past, the writer became convinced that a second influenza epidemic usually follows the first at an interval of thirty-three weeks, providing the thirty-third week does not fall between June and December, in which case the recurrence may be expected at the end of sixty-six, or perhaps ninety-nine weeks; in accordance with this rule he predicted that the fall epidemic of 1918 would recur in January or February, 1920, and the figures of the Census Bureau show that the return of the epidemics in Chicago, Washington, and New York this winter took place exactly sixty-six weeks after the mortality peak of 1918 in those cities.

This periodicity suggests that the pathogenic organism of influenza, whatever it may be, not only has the power of reproduction continuously for a long period, if susceptible persons are exposed, but also has the power of developing in cycles of thirty-three weeks or a multiple of the same. The present recurrence, the writer in the Bulletin suggests, might possibly be explained on the hypothesis that the immunity conferred by one attack lasts thirty-three or sixty-six weeks—a very improbable supposition, and one that is contradicted, he adds, by the fact that most of those attacked in 1918 were still immune in 1920, while many of those not attacked in 1918 contracted the disease upon its return.

"The more reasonable explanation seems to be that the present epidemic is due to a definite cyclical regrowth of the infecting organisms from the seed of the former epidemic. Definite cycles of development are common in the known animal and vegetable world; some plants flower annually, some biennially; the malarial organism may complete its cycle in two or more days; the locust requires in some cases seventeen years. Similarly the organism responsible for our recent pandemic may complete its cycle in thirty-three weeks or perhaps sixty-six weeks."

This recurrence of the disease after sixty-six weeks would seem to strengthen the belief that the epidemic of 1889-90 and that of 1918-20 are identically the same and have a common etiology, although the predominant clinical manifestations differ, the present epidemic being characterized by lung complications chiefly, while the heart and nervous system suffered more severely in the pandemic of 1889-90. Dr. Brownlee's observation, if confirmed in future pandemics, will be an interesting addition to the mysterious and too little studied subject of the periodicity of disease.

DIVERTICULA OF THE BLADDER.

THE complications to which a diverticulum of the bladder may give rise are mechanical, infectious, calculous, and neoplastic. The first include rupture, compression of the surrounding viscera, hernia, and inversion. Rupture of a diverticulum is very uncommon, but it can occur from exaggerated distention of the bladder. When rupture takes place the liquid contents of the diverticulum—a liquid always septic—may enter the peritoneal cavity, resulting in rapid death from septic peritonitis, even when surgical interference is prompt. But if the rupture takes place into the perivesical fat the infection will probably remain localized because of the extremely thick adhesions which bind the diverticulum to the surrounding structures; therefore, a collection of pus forms which, if left untreated, will open through the abdominal wall. Compression of the neighboring viscera is the most frequent mechanical complication met with and does not depend upon the size of the diverticulum even when very large. The bladder, ureters, and rectum are the organs involved. Retention of urine from compression has been known to occur, while when the ureters are compressed the consequence will naturally be distention and the resulting ascending infection of the kidney. The resulting pyelonephritis is frequently bilateral and death will soon occur. In other instances pyonephrosis or sclerous atrophy of the kidney has been observed. Compression of the rectum by a diverticulum has been known to cause constipation, while hernia of this malformation must not be mistaken for a cystocele. When a diverticulum forms an inguinal hernia it presents a narrow neck which does not correspond with a portion of the tract of the hernia. English has reported three instances of diverticulum in femoral hernia. A hernia of a diverticulum does not usually give rise to any functional symptom; disturbances of micturition are absent while the physical signs in no way differ from those encountered in intestinal or omental hernia. Consequently, the diagnosis is usually made during operation; the diverticulum may contain calculi or become strangulated. Inversion of the diverticulum within the bladder has once been reported.

Infection of a diverticulum is the most common complication. The process may remain confined to the cavity of the malformation, resulting in a diverticulitis, but the danger resides in the extension

of the infection to the upper urinary tract. A diverticulitis may exist without cystitis. This does not imply that there has not been a cystitis, but while the vesical process has subsided under proper treatment, the incompletely drained cavity of the diverticulum containing stagnant urine offers an eminently favorable medium for the pullulation of bacteria so that infection is not long in attaining a very considerable degree. The clinical signs of diverticulitis are those of cystitis, but there are others which are peculiar to the process. Thus the urine will at times be limpid, at others cloudy, or when voided spontaneously it will be clear, while that withdrawn by the catheter is distinctly purulent. The process may occasionally assume a very acute aspect, recalling by its local and general phenomena a perivesical phlegmon. Perforation or gangrene is uncommon, but should either occur the consequences are naturally serious, especially when the diverticulum does not adhere to any of the surrounding structures which might otherwise limit the extent of the infection. Infection of the upper urinary tract is favored by compression of the ureter by the diverticulum. Dilatation first occurs, soon followed by infection, usually resulting in a pyonephrosis; but if the ureter is occluded a pyelonephritis—usually bilateral as is the case in pyelonephritides from distention—ensues.

A rare but very serious infectious complication is thrombosis of the iliac vessels which may cause fatal embolus. The presence of calculi in a diverticulum is common, particularly when infection exists, in which case they are phosphatic, but uric and oxalic calculi have also been found. Radiography is the best diagnostic means at our disposal, but it will probably give inexact data as to the number of stones contained in the abnormal pocket. Intradiverticular neoplasms are extremely rare and are discovered only by cystoscopy. Clinically, they give rise to severe hematuria which, when intermittent, may be suspected of being renal in origin.

ELECTRICAL BURNS.

AN electrical burn is a circumscribed lesion of the skin and underlying structures, produced by direct contact of a conductor with the body. It is distinguished from lesions due to radiation from an electrical focus or caused by the arc which flashes between two conductors. In the first case the violet and ultraviolet chemical rays are in play, while in the second it is the spark. What influences its production quite as much as its gravity is: (1) The type of current, the continued current adding an electrolytic action to the thermic action; (2) the intensity of the current which is in relation to the voltage which develops the quantity of heat disengaged, the thermic effect being proportional to its square; (3) the density of the current, that is to say, its concentration over a small surface of contact; (4) the resistance offered by the human body—principally the skin especially when dry, thick, or callous; (5) the duration of the contact, prolonged in some cases by contraction of the flexor muscles.

Electrical burns do not offer any very special clinical characters until the third degree has been reached. They occasionally appear in the form of black parchment-like sloughs with well-defined borders, but usually they are crater-like, as if cut out with the curette, with dry distinct borders and presenting the same degree of gravity in all. They are usually painless, without inflammatory reaction or congestive phenomena common to ordinary burns, excepting in the rather rare cases in which they are extensive and deep. The evolution is usually aseptic or at least there is not much suppuration, and cicatrization, which is long in taking place, results in a smooth, elastic scar devoid of deep fibrous adhesions. Unless the loss of tissue is very considerable repair takes place readily, otherwise contractures and vicious attitudes of the limbs involved will result, causing functional incapacity. Complications are very rare.

Given these characters and evolution, treatment will be of the simplest kind; an antiseptic dressing and the application of tincture of iodine being about all that is essential. In cases where the muscles have been carbonized or the bones necrosed, surgical interference will be required, but the operation is facilitated by the distinct limits of the slough. The treatment of the commotion with loss of consciousness frequently arising from these burns is that of asphyxia in general.

Death is the effect of the continued or alternating current, the kind matters little. With the alternating current the most dangerous frequency is between 50 to 100 interruptions per second; the intensity is always a factor of gravity, since the force of the current increases with it. For the voltage it is different, low voltages are more dangerous than the high. Their action is not the same; the low tensions produce death by arrest of the heart, the medium by arrest of the heart and respiration, and the high by respiratory inhibition. The part played by the burn is to shield the victim from the effects of the current if this is prolonged enough to cause death, because the lesion produced at the point of contact increases the resistance opposed at this point to the passage of the current and, consequently, plays the part of an interrupter, so that the burn—a local effect, tends to avert death—a general effect on the organism.

THE DIAGNOSIS OF DEXTROCARDIA.

CULCER has recently collected a total of fifty-eight cases of dextrocardia and found that in twenty the inversion was total and uncomplicated, while seven others were total inversions with cardiac malformations. There were eleven cases of dextrocardia with malformation of the heart and in twenty others the dextrocardia was pure. Therefore, contrary to what might have been expected, dextrocardia and simple pure inversion are more common than dextrocardia with concomitant cardiac malformations. Of fifty-

seven cases—the sex was not stated in one—there were seventeen females and forty males; therefore, the masculine sex represents 66 per cent. of the cases. Of the twenty cases of simple inversion nineteen of the patients were between twelve and forty-six years of age and one was a child of eight. Of the seven cases of total inversion with cardiac malformation, three subjects were less than three years old and four between thirteen and twenty. Finally, of the eleven cases of dextrocardia with malformations, there was one woman seventy-six years old, one male of forty-one years, and nine children below the age of ten.

Therefore, it would seem that, when dextrocardia or total inversion is simple, it has no apparent influence on the patient's life, and an advanced age may be attained without the presence of the anomaly being known. But when these conditions are combined with congenital cardiac defects, life becomes impossible or at least is considerably shortened, with very rare exceptions.

An attentive examination will lead to a correct diagnosis of dextrocardia, and it would be a gross error to mistake the cardiac beats for a pulsatile empyema, although a right-sided pulsatile empyema is also uncommon. In this case the true apical shock should be visible in its proper place. It is common knowledge that a pulsatile empyema may often be accompanied by an extrathoracic tumor or a pneumothorax, and that their own peculiar symptoms are sufficient for the diagnosis. The extent of cardiac dullness to the right might lead one to suspect a dilatation of the heart, when in reality the case is one of dextrocardia; but such a diagnosis surely could occur only as the consequence of gross carelessness.

When the diagnosis of dextrocardia has been made, the question arises as to whether it is acquired or congenital. If at the same time there is a total inversion of the viscera the cardiac anomaly will, in all likelihood, be congenital, but a too hasty conclusion must not be formed because the heart need not necessarily be inverted when the viscera are, as inversion of the abdominal organs only is known to occur.

It follows then, that in order to arrive at a certitude by an attentive thoracic examination, one must eliminate mediastinal growths pushing on the heart; mediastinitis, which may create adhesions and consequently a retraction producing a displacement of the heart to the right; and lastly, left-sided pleurisy or pneumothorax pushing the heart to the right. Right-sided pulmonary affections with adhesions and consequent retraction, such as an old pleurisy, empyema, pneumothorax, or tuberculosis, may cause some displacement of the heart to the right.

The cause of dextrocardia, like that of all congenital visceral transpositions, is unknown. Carpenter maintained that dextrocardia was hereditary, but this is manifestly incorrect, for out of Culcer's fifty-eight cases there were only four in which this relation existed.

Vagotonia.

A Spanish physician, Dr. A. Mut, has recently rewritten this subject from the pioneer labors of Langley, followed by those of Eppinger and Hess, Falta, Froehlich, Castellino, and others. During the war, activity along this line was not pronounced and the doctrines of Eppinger and Hess were not accepted by many clinicians. From Mut's paper, which appears translated in the *Archivos de Biologia* of Sao Paulo, Brazil, for August-September, 1919, iv, 38, we abstract the following account of vagotonia as revised up to date: The child with this makeup recalls the scrofulous individual of two generations ago, although the facies and the swollen glands of the neck are found in association with cold and cyanotic extremities and vasomotor instability; in other words, torpid and erethetic scrofula combined. There is a predisposition to eruptions of the scalp and in adolescence a tendency to acne The subjects present a state of irritable weakness and are easily fatigued. Other somatic conditions mentioned are adenoids and enlarged tonsils, myopia, and the sign of Graefe (lack of synergy between movements of the eyelids and those of the eyeballs), instability of the cardiac action as shown by palpitation, tachycardia, etc. There are, further, geographical tongue, granular pharyngitis, salivation, air-swallowing, irregular and capricious appetite, crises of constipation alternating with diarrhea, and membranous colitis. Among genito-urinary symptoms are phosphaturia, pollutions, and precocious ejaculation. Reflexes are exaggerated and tremor may be seen at times in various muscles, as the tongue and eyelids. The skin is disposed to flushing, cyanosis, and dermographism. Upon this substratum many phenomena known collectively as hysterical may develop. Of especial clinical interest are cardiac crises, such as paroxysmal tachycardia, gastric crises, and asthmatic paroxysms. Diagnosis is made by drug action, the subject reacting strongly to pilocarpine, while atropine should always favorably affect a true vagatonic. Drugs which produce sympathicotonus like adrenalin are also indicated. Curative treatment is limited largely to hydro- and physiotherapy. The reader will note the marked parallelism between vagotonia in childhood and Czerny's exudative diathesis.

Improvement in Cancer Statistics.

At the Gynecological Clinic at the University of Berne cancer figures for the period 1914-1918 show a great improvement over those of 1908-1913. During the first named period radiotherapy has been extensively employed but the improvement appears to be due largely to the fact that patients come earlier for treatment so that many more cases and more operable cases come to the Clinic than in other days. The material has in fact almost doubled and while the operative mortality in the old period for cancer of the cervix reached the high figure of 41.6—Wertheim's operation—it has been during the last period but 10 per cent. The secondary mortality shows only a slight betterment. While the survivors in the old period number only 12 per cent., in the latter period the figure is 40 per cent., subject of course

to discount for the nearness of some operations to the present time. In the first period in point of time the average survival was 12.2 months, while in the second period the corresponding figure was 18.3. This improvement is due largely to prophylactic radiation after operation. A special classification is inoperable cancer of the porto vaginalis. In the old series not much could be done beyond simple palliation, but in the second series of cases radiation was available. Some patients died soon after admission, but 90 per cent. were treated and the average survival was over nine months. Some patients in whom both radium and *x*-rays were used showed a longer interval—as much as 12 months. The author—Steiger in the *Correspondenz-Blatt für Schweizer Aerzte* for November 6, 1919, xlix, 45—is inclined to favor the *x*-rays above radium, as the initial gains from the latter are often dearly obtained, he says, at the price of fistulæ, etc.

Masculine Pseudohermaphrodism with Normal Vagina.

While a normal vulva is common in male pseudohermaphrodism it is not often that the vagina is perfectly developed, for the absence of a uterus usually involves more or less deformity of the vagina, from total absence to a short rudimentary canal without the structure of the normal organ. Hence these pseudo-females are not often able to have sexual relations with men. The following case reported by Schwartz in *Le Bulletin Médical* for December 6, 1919, xxxiii, 54, should be of interest. The subject was ostensibly a woman aged 25 who presented herself for painful bilateral inguinal tumors. On one side the tumor proved to be a hernia but in the opposite side was found a testicle with epididymis and vas deferens. Operation on the first side showed that a testicle was also present in the hernial sac. The vulva was perfectly formed and the vagina was ample in width and about 12 cm. deep, ending in a cervix uteri. There was a uterus but apparently it had no cavity and an imperforate os. Menstruation had naturally never been established. The *embonpoint* hair of the head and pilous system in general, and the breasts were those of a woman, but the voice was rather masculine and the feet large. The individual was attracted to males, had been married two years and had normal and pleasurable sexual relations with the husband.

News of the Week.

Pharmacopœial Convention.—In harmony with the requirements of the by-laws, attention of interested parties is called to the meeting of the Tenth Decennial Pharmacopœial Convention of the United States, to be held May 11, 1920, at the Willard Hotel, Washington, D. C. All incorporated bodies and other institutions entitled to membership in this convention are entitled to apply at once to Dr. Noble P. Barnes, Arlington Hotel, Washington, D. C., for the necessary blanks for membership. It is important that all applications for membership be in the hands of Dr. Barnes at least six weeks before the date of the meeting.

Colorado Cancer Control Campaign.—Under the leadership of Dr. Charles A. Powers, Chairman of the Colorado Committee of the American Society for the Control of Cancer, that State is conducting a thorough educational campaign by means of lectures and the distribution of literature. Twelve hundred copies of the booklet, "What We Know About Cancer," have been sent to physicians and surgeons throughout the State, embracing the entire membership of the Colorado State Medical Society, the Homeopathic Medical Society, and about two hundred and fifty other practitioners. Public Health and Red Cross nurses have been circularized, and the pamphlets, "Cancer-Facts Which Every Adult Should Know," and "Fourteen Points About Cancer," have been issued in large numbers. During October, November, and December the twenty-two lectures delivered by the various members of the lecture staff were heard by 1,345 individuals.

Appropriation for Influenza Fight. — The New York Legislature appropriated fifty thousand dollars to combat the influenza epidemic by relieving the urgent demand for physicians and nurses.

Rise in Price of Coffins.—The recent advance in the price of coffins announced by the National Casket Company of Long Island City was denounced by the Commissioner of Health of New York City as coming with bad taste and meriting suspicion, since it is coincident with the increased need for coffins due to the country-wide epidemic of influenza. The Commissioner has declared his intention of bringing the matter to the notice of the Federal Government.

Campaign Against Rats in Great Britain.—The new British rats and mice act compels occupants of land to keep their premises free of rodents, a penalty of £5 being imposed for failure to do so. According to press reports, the people of the United Kingdom, young and old, have embarked on a vigorous campaign of extermination.

Red Cross Workers Prisoners of Bolsheviki.—According to cable advices from Vladivostok the following Red Cross workers were captured recently by the Bolsheviki in Siberia: Dr. W. H. Ford of Kingston, Okla. (probably); Dr. J. N. Mehill of Jaroso, Col.; Otto W. Lowe of New York, and Edward E. Charette of Stockton, Cal. Request for their release has been forwarded to the Russian Soviet authorities through the Czechs. The prisoners are not believed to be in any danger, according to the cable advices, this opinion being founded on reports from the newly conquered parts of Siberia indicating that the Bolsheviki are pursuing a liberal policy toward prisoners.

Health Campaign Among Boys. — The United States Public Health Service has started a campaign in America to reach all boys between the ages of 15 and 20 years and interest them in a campaign to keep themselves physically fit. Surgeon General Ireland of the Army, and Surgeon General Braisted of the Navy have taken a keen interest in this movement, which has the backing of the Young Men's Christian Association, churches, welfare organizations, and educators throughout the United States.

County Health Work in South Carolina.—Seven counties of the Palmetto State have agreed to

make the necessary appropriations to carry on a county health work during 1920. The State Health Department plans to conduct this work in eight counties during the present year.

Unlawful Practice Cases in New York City.—The County Medical Society announces that as the collection of evidence and the prosecution of cases of unlawful medical practice occasion an expense which the income of the Society does not justify, and as such activity is entirely voluntary and not obligatory on the part of the Society, it has been decided that in future all cases of unlawful practice which come to the attention of the Censors which, in their judgment, require investigation or prosecution, will be forwarded to the Police Department of the city and the District Attorney. The Society, therefore, will not hereafter assume the expense of investigating complaints or prosecuting cases.

Cripples Cared For.—The New York Society for the Relief of the Ruptured and Crippled reports that 12,000 new patients applied for treatment at the dispensary during the past year, and that 1,600 are treated yearly in the hospital.

Influenza in Twenty States.—The United States Public Health Service announced on January 27 that influenza is prevalent generally in twenty States, and has made its appearance in several others.

Anesthesia Research Society Formed. — Announcement is made of the organization of the National Anæsthesia Research Society, with the avowed purpose of collecting data and prosecuting original research in this field of medicine. The Research Committee, which will have the supervision of original work and the editing of material designed for the profession and professional press, is headed by Dr. F. H. McMechan of Avon Lake, Ohio, editor of the Quarterly Supplement of the American Year Book of Anæsthesia and Analgesia. W. J. Jones, D.D.S., of Columbus, Ohio, president of the Inter-State Anæsthetists' Association, is the secretary, and will have an active part in the work of the committee. Representative anesthetists of the country who have distinguished themselves by research and progress in their field are being invited to join the committee.

New Tuberculosis Association.—The anti-tuberculosis work in New York City which, for the past seventeen years, has been thoroughly and energetically carried on by the Committee on the Prevention of Tuberculosis of the Charity Organization Society, has been taken over by a new and larger corporation, the New York Tuberculosis Association, Inc. All the members of the old committee including such prominent workers in the tuberculosis field as Dr. Herman M. Biggs, State Commissioner of Health; Dr. Royal S. Copeland, Health Commissioner of New York City; Mr. Lee K. Frankel, Dr. S. S. Goldwater, Mr. Thomas W. Lamont, Dr. S. A. Knopf and others are members of the Board of Directors of the new association. Dr. James Alexander Miller is the president of the association and Mr. Homer Folks is the vice-president. Dr. John S. Billings, long connected with tuberculosis work in New York City, is the director. Among the secretaries so far appointed are: Mr. G. J. Drolet, statistician; Miss Gretta Jones, relief organizations; Mrs. Josephine Toering, tuberculosis dispensaries; Mr. E. C. Rybecki, labor; Mr. David Ryan, publicity.

New Hospital for Panama.—The new National Hospital of the Republic of Panama is now under construction. The hospital will cover fourteen acres on a high point facing the Pacific in the suburbs of the city of Panama, and will be composed of eleven buildings of reinforced concrete. The capacity of the hospital will be 600 patients. The construction of the hospital is in charge of Major Edgar A. Bocock, M. C., U. S. Army, who is now superintendent of the Santo Tomas Hospital, Panama. He will take charge of the new hospital upon its completion.

Aid for Poland Typhus Victims. — The Red Cross Societies of Belgium and Sweden have joined with five other countries in an effort to prevent the threatened spread of typhus fever over Western Europe. The Swedish Red Cross, according to cable advices, has asked its Government for a subsidy of 1,000,000 crowns to combat the epidemic. Belgium is expected to send doctors and nurses to Poland.

University of Warsaw Research Laboratory.—Through the agency of the American Red Cross a new medical laboratory has been opened in Warsaw. The equipment, which is new throughout, is complete from the simplest phial to the largest and most expensive instruments. The laboratory, under the direction of Major Bruce Mohler of Fremont, Ohio, is in charge of Dr. Placida Gardner of Los Angeles, Cal., with Dr. Gladys Vaughan of Wolfeville, N. S., as chief bacteriologist.

Quinine for Lepers.—The American Red Cross recently received acknowledgment, through a Sister of Charity, of a case of quinine sent to the leper colony at Tarafangana, Madagascar. The gift was gratefully received at a time when, according to the Sister, "the shortage of supplies was hampering our work of charity in this poor mission of Tarafangana."

Recurrence of Typhus in the Balkans.—Sixty-two American Red Cross nurses are now on duty in Serbia and Albania, battling against the recrudescence of typhus, which has made its appearance in the Balkan States. Additional American aid was found necessary because of the lack of hospital facilities and the difficulty in teaching native nurses to handle typhus cases properly. Failure to wear "typhus robes" and to use proper sanitary precautions are some of the conditions that have been found in districts where typhus was thought to have been stamped out.

Antituberculosis Campaign in France. — The Rockefeller Foundation has decided to extend its work along the line of a post-bellum campaign against tuberculosis in France, particularly in the Chateau-Thierry and St. Quentin areas, where more than half the old population has returned to the ruined villages. The same methods adopted by the Foundation in America will be employed in France, and close cooperation will be maintained with the American Red Cross and the French relief agencies.

"Sickroom Attendants."—The plan of Charities Commissioner Bird S. Coler to establish a training

school for "sickroom attendants," with the object of relieving the shortage of nurses, has been approved by the Woman's Municipal League, which issued the following statement: The plan gives a training course of nine months, after a post-graduate course of three months. During all this time expenses are paid, uniforms are furnished, and students receive $35 a month. The only educational requirement is ability to read and write well enough to keep simple bedside records. Women of any age above 18 may enter these schools for trained attendants, a fact which opens up a field for middle-aged women and widows who find themselves suddenly deprived of means of support.

Liquor for Use in Influenza Epidemic.—The Bureau of Internal Revenue has regulations regarding the use of intoxicating liquors during the influenza epidemic which makes it incumbent upon the physician who prescribes and the pharmacist who sells the liquor to procure a permit for the purpose. A warning is issued at the same time against profiteering in the sales.

Infant Mortality Rate Reduced.—In making its annual report for the year 1919 the Diet Kitchen Association of New York City claimed its share of credit for the reduction in the mortality rate of infants under one year of age. For each one thousand births there were only eighty-two deaths, the lowest infant mortality rate on record for the city. Through its eight milk and health stations, pre-natal work among expectant mothers and baby welfare work the association assisted in this reduction. During the past year 8,071 babies under two years of age; 1,695 children between the ages of two and six; 6,780 mothers and 882 expectant mothers, as well as 899 social service cases, have been under the care of this organization.

Red Cross Society Elects Officers.—The New York Chapter of the American Red Cross Society has elected the following officers: Col. James H. Perkins, chairman; Mrs. William Kinnicutt Draper, vice-chairman; Homer Folks, executive officer; Mortimer N. Buckner, treasurer; Henry J. Cochran, assistant treasurer; John Bassett Moore, secretary; Alfred L. Curtiss, assistant secretary; executive committee, Mortimer N. Buckner, chairman; John G. Agar, Mrs. August Belmont, George Blumenthal, William C. Breed, George S. Brewster, Robert W. De Forest, John S. Ellsworth, Homer Folks, Mrs. John M. Glenn, John M. Glenn, Walter Jennings, Paul U. Kellogg, Grayson M. P. Murphy, Miss Mary Parsons, Mrs. Whitelaw Reid, Mrs. Austin Baldwin, George M. Woolsey; Mrs. Leonard Wood, honorary member.

Orthopedic Clinics.—The North Adams (Mass.) Hospital has arranged with Dr. J. E. Goldthwait of Boston, for the holding of monthly orthopedic clinics under his direction. The first of the clinics was held January 21.

Nurse Held for Manslaughter.—According to the report of an inquest filed in the Superior Court, Dedham, Mass., January 27, the nurse who attended a patient in a private hospital in Wellesley was held responsible for the patient's death, which "was due to multiple scalding," 95 per cent. of the body being badly burned. The court held that death "was contributed by the unlawful negligence" of the nurse.

Nobel Prizes Declined.—The Nobel prizes for 1919 in economics and medicine, which were offered to Frenchmen, have not been accepted. The refusal was based upon the fact that the Swedish body saw fit to confer the prize for chemistry upon Dr. Haber, the inventor of the poison gases used by the German army during the World War.

Laboratory Diagnostician Needed. — The New York State Civil Service Commission announces an examination, to be held February 28, for the position of Assistant Laboratory Diagnostician. The salary is $2,000. Minimum age 25 years; preferred ages 34 to 40 years. A degree in medicine is required. Candidates must have a thorough knowledge of bacteriology, immunity, and vaccine and serum therapy. They should have had at least one year of practical experience in laboratory diagnosis. They will be examined in the subjects of infection, immunity, and vaccine and serum therapy and laboratory diagnosis. Subjects of examination: Written examination relating to the duties of the position, relative weight 4; education and experience, relative weight 6.

Dr. Hugh S. Cumming of Hampton, Va., has been appointed to succeed Dr. Rupert Blue as Surgeon General of the United States Public Health Service. Dr. Blue's term expired January 15. Dr. Cumming, who was for several years quarantine officer at Hampton Roads, is now in Europe studying typhus fever conditions.

Dr. J. M. T. Finney, Professor of Clinical Surgery at Johns Hopkins University Medical Department has declined to accept the professorship of surgery at Harvard University Medical School.

Dr. D. M. Marvin has removed his office from 12 West 130th Street to 829 Park Avenue, New York City.

Medical Society Elections.—The WATERBURY (CONN.) MEDICAL ASSOCIATION, at its annual meeting held January 12, elected the following officers for the ensuing year: *President,* Dr. Edward W. Goodenough; *Vice-President,* Dr. M. J. Lawlor; *Secretary,* Dr. G. A. Gosselin; *Treasurer,* Dr. C. S. Robbin; *Assistant Treasurer,* Raymond F. Frapria.

The KENNEBEC COUNTY (MAINE) MEDICAL ASSOCIATION, at its annual meeting January 20 elected the following officers for the ensuing year: *President,* Dr. S. C. Badger of Winthrop; *Vice-President,* Dr. George A. Coombs of Augusta; *Secretary,* Dr. S. J. Beach of Augusta; *Treasurer,* Dr. H. E. Thompson of Augusta.

Charitable Bequests.—By the will of the late Emma Feuchtwanger of New York City the sum of $75,000 was left to charities. Among the institutions named are the Montefiore Home; Sanitarium for Hebrew Children; Hebrew Infant Asylum; Blind Asylum of New York; New York Skin and Cancer Hospital; Servants of Relief of Incurable Cancer; Beth Israel Hospital; Hebrew Relief Society, and Henry Street Nurses' Settlement.

Obituary Notes.—Dr. CHARLES A. CHURCH of Millbury, Mass., died January 14 as the result of injuries received when his automobile was struck by a freight train. Dr. Church, who was in his sixty-fourth year, was graduated from the University of Vermont College of Medicine in 1884.

Dr. Frank Lawrence Cochrane of Brooklyn, N. Y., killed himself January 16 by firing a bullet through the mouth, into the brain. Death resulted almost immediately. He was 43 years of age. He was graduated from the College of Physicians and Surgeons in 1900. He was a member of the American Medical Association.

Dr. Robert Kearns of Middletown, N. Y., died January 22, at the age of 55. He was graduated from the College of Physicians and Surgeons, New York City, in 1888, specializing in otolaryngology. He was a member of the American Medical Association.

Dr. Daniel J. McSweeney of Boston, Mass., died January 19, at the age of 52. Death was due to cardiac disease. Dr. McSweeney was graduated from Harvard Medical School in 1903. He was a member of the American Medical Association, the Massachusetts Medical Society, and various other organizations.

Dr. Isaac Smith of Peel Tree, W. Va., died of heart disease January 16, at the age of 68. He was graduated from the Kentucky School of Medicine, Louisville, in 1876.

Dr. O. T. Logan, pioneer medical missionary of Hunan Province, China, was recently killed at Chengtu while visiting his friend, General Y. H. Feng, according to advices received at the "Yale in China" offices at New Haven. Dr. Logan had left instructions that his body should go to the medical school conducted by Yale men at Changsha, to provide material for study by the seventy students in the school. He is well known through his discovery of a variety of fluke.

Correspondence.

THE CHRISTIAN SCIENCE PSYCHOSIS.

To the Editor of the Medical Record:

Sir:—Christian Scientists in general will be grateful for the modicum of fairness, however deeply buried under the mass of condemnations of their religion, which appeared in the article in your issue of December 27, entitled "The Christian Science Psychosis." Perhaps it has not occurred to the doctor that there may be many persons, more spiritually receptive than he, who find nothing "ambiguous" or "incomprehensible" in the textbook of Christian Science. It should be remembered that the great majority of Christian Scientists have become students of this religion because of very definite results, usually in the form of healing of disease and frequently after the failure of all material means. Moreover, it is not an unusual attitude to attribute mental unsoundness to all who differ from one in the important relations of life, religion, politics, healing methods, etc.; and one easily believes from reading the article in question that such a belief obtains with this critic.

While manifestly it would be impossible for me to affirm or deny the allegations regarding the three cases he describes, there is enough evidence at hand to prove irrefutably the healing power of Christian Science in so-called mental diseases. And not a few of such healings have been recognized by the medical profession. My attention has been called quite recently to two cases of healing by the same Christian Science practitioner of so-called insanity where the patients were confined in asylums. Both responded in a very short time after spiritual help was had, and both had been long under medical treatment without favorable results.

Regarding his statement as to the kind of people who become students of this religion, it may be asserted that Christian Science numbers among its earnest students in this country and abroad many persons who are adjudged by their fellows of sufficient mental soundness and intellectual accomplishment to warrant their elevation to high places in the affairs of their respective countries. The Army and Navy have a goodly sprinkling of Christian Scientists. There are numerous lawyers, judges, professors, statesmen, editors, teachers, business men, and not a few from the ranks of medicine and the ministry among its followers and workers. To accept the statement of this critic, all of these persons must of necessity be subject to some form of mental aberration.

Christian Scientists are satisfied to work out their salvation in accordance with the teachings of the Man from Nazareth, who not only healed all manner of diseases but, as a proof of their discipleship, enjoined upon His followers the necessity of like accomplishment. Christian Scientists have accepted this injunction of the Master in good faith and are earnestly striving to emulate His works. That they have already accomplished much is quite generally recognized by unprejudiced observers.

OUR LONDON LETTER.

(From Our Own Correspondent.)

London, Jan. 23, 1920.

Falling Birth Rate in Great Britain.—A falling birth rate in existing circumstances is no more nor less than a national calamity. It is obvious and especially in a country like Great Britain, whose manhood has been so grievously depleted by the war, that the need for conservative child life is among the most insistent of social problems. In 1918 the national increase of population by excess of births over deaths was, in England and Wales only 50,783 compared with an annual average for the preceding five years of 287,671, and as a result of the influenza epidemic which cost the country 100,000 lives in 1918 alone, there was in the last quarter of the year an actual excess of deaths over births of 79,448. It is gratifying then to learn that the various public activities associated with the care of mothers and infants are steadily expanding. In the last report of the English local government board's medical officer, the necessity is pointed out of still further concentrating on measures which will reduce the mortality of children born, and increase the number of those born alive in contradistinction to those stillborn. There is no doubt that a good deal of this mortality is preventable, and in this direction the principal hope lies of restoring the balance of the population in the presence of a continuously falling birth rate. The infant mortality rate for the whole country in 1918 was 97 per 1,000 births; in London it was as high as 107. Persistent efforts have been and are being made to stimulate local authorities to

secure full notification of all births in their areae, and it is encouraging to note that there has been a general improvement in this respect. Before the war the facilities for caring for expectant mothers were so good and so extensive that they were exerting a most beneficial influence upon the birth rate, and upon the quality of the infants born. Unfortunately these facilities, especially the provision of centers at which expectant mothers could attend, were greatly hindered by the society of medical practitioners during the war. However, the indications seem favorable now that medical officers of health and local authorities alike, are alive to the necessity for such work. By caring for ill-nourished mothers, under special arrangements of the food controller, immense benefit was reaped by mother and infant. Expectant and nursing mothers were supplied with milk and extra rations of meat and butter. Nursing mothers had also the privilege of using the newborn infant's ration card for obtaining meats, fats, and sugar. These arrangements were additional to those made to secure priority in the supply of milk for children under five years of age and for othes especially needing it. It is almost superfluous to state that these measures were of the greatest value in sustaining expectant mothers through a trying period, and in securing for children enough milk to keep them in health. Also, indirectly by improving the nutrition of the nursing mother, preserving the life of the suckling infant at an age when in the absence or deficiency of its natural supply, a change to artificial feeding was exceptionally dangerous.

According to the report, at least 34 per cent. of the total infant mortality is ascribed to premature birth, congenital defects, atrophy, debility, and marasmus. In industrial areas, in particular, large numbers of children are born to die at or within a few days of birth. These children present no gross defects or lesions of the vital organs, but the tissues have never been properly nourished. Presumably it is the nutrition and environment of the mother during pregnancy which is at fault, but whether there is a defect or deficiency of the vital principles, the so-called vitamines, or simply of adequate nourishment, and how far environment, such as housing conditions, is responsible, is a matter for future investigation. At any rate, there can be no doubt that the ordinary diet of many mothers in industrial districts is so poor in quality that it is surprising they can maintain life on it, much less sustain the unborn infant and provide it with sufficient stored-up food to carry it through the period when it becomes exposed to the external influences involved in a separate existence. The report gives its authority to the theory that the prevalence of rickets and acidosis in young children is largely due to these same influences. It may be stated that maternity and child welfare are becoming universal in England and Wales. Action has been taken by all county councils and all metropolitan boroughs, and there are now very few of the smaller authorities which have not come into a county scheme or are not carrying on work of their own. The absorption of the work of voluntary associations by local authorities and the taking over of schemes initiated by the smaller local authorities by the county councils still continue. The extension of the work undertaken by the county councils and the larger urban authorities has led to the engagement of a number of whole-time assistant medical officers of health for maternity and child welfare only, or for this work in combination with school, tuberculosis, venereal disease, and other medical work. It is interesting to gather from the report that the number of health visitors, whole and part time, increased from 2,555 in 1917 to 3,038 in 1918, and the number of maternity and child welfare centers from 1,278 to 1,365. Through the efforts of the county councils, working in cooperation with the county nursing associations, the provision of midwives continues to make progress, and many rural areas which were without a midwife have now been provided with this service. The number of midwives employed directly by the local authorities is increasing, but is still very inadequate to the needs. On this point, the report says: "There is no doubt that, as a consequence of the difficulty in obtaining the services of a midwife, doctor, or monthly nurse, in many rural areas the mortality of both the mother and newborn child is unduly increased, and that if these services were more freely available, the low infant mortality of rural districts could be still further and considerably reduced." The need for "home helps" during the lying-in period is becoming very generally felt. A number of both local authorities and voluntary associations have already engaged them, and others are making arrangements for that purpose. There has been a considerable increase in the number of crêches and day nurseries. Since the cessation of war conditions, and the release of married women from industrial employment, some of these have been closed, but an increasing number of local authorities have become interested in the subject, as a means not merely of caring for the child while the mother is at work, but for improving the health of children who require special attention, and of instructing mothers, and girls in attendance at school, in the proper care of the young infant. There has also been a considerable development of dental assistance for children and nurses and expectant mothers. During 1918 this was largely taken up by many of the populous provincial urban authorities and by the county councils for rural areas.

I have intentionally dwelt at some length upon the measures being taken in England to increase the birth rate and to preserve and improve the quality of infants born, because these are matters which concern every civilized country and especially an industrial country such as the United States largely is. Conditions in the large cities and industrial areas of America closely resemble those of Great Britain, and the need for conserving infant life, or, at any rate, for maintaining the quality of infants born at a high standard is almost as urgent in one country as in the other. Consequently, measures which have proven satisfactory in Great Britain would appear to be worthy of adoption in America. Maternity and infant welfare schemes which largely owe their origin and development to Dr. Eric Pritchard of London, have already worked well and in this era of preventive medicine will undoubtedly in the future have even greater success. There are two main objects of medicine at the present time:

one is to rear a healthy race, and this can only be done by caring for expectant mothers, nursing mothers and infants, and by dispelling the ignorance which exists among mothers generally as to the proper bringing up of children. The other main object of medicine is to prevent disease.

The Woman of To-day.—Dr. A. I. Schofield lectured at the Victoria Institute on January 19, on "the Psychology of the Female Mind." He said, in part, that the new woman was better than her precursor and the wonder was that she had been so long in developing. But the remarkable lack of women's interest in their own minds was, he said, a very curious point. He still waited for a true concept of the female mind written by a woman. The subject was of the first importance, for it was not too much to say that the future of England largely depended on the quality of women's minds to-day. Women generally were more spiritual as well as more emotional than men, though the difference was not so well marked as in earlier ages, owing doubtless to the slow approximation in type of men and women, which in its turn was due not only to the emancipation of women, but to the invention of machinery, which rendered men's greater physical power comparatively negligible in industry and so acted as a great leveler of sex. Differences in respiration between the sexes, which were carefully described and illustrated with diagrams fifty years ago, had almost disappeared together with the woman's small waist of which they were the product. Not all the psychological differences between the sexes had, however, been yet extinguished. Dr. Schofield still found women less scrupulous as to means than man, less careful to "play the game," though she was more scrupulous as to ends. She still relied more than man on intuition and instinct, and often with better results. One of the subtle reasons of the social ascendancy of man was to be found in dress. In past ages, as in all the animal world, it was the male who dressed to attract, the choice of a male resting with the female. Hence, the gorgeous plumage of the male bird and the extraordinary decorations of the early savage wooer. All this had been changed, but when once a woman's independent economic position was assured, she would probably select her mate in a way that would now, with our false standards of conduct, be considered positively indecent. Considering, however, that she would be the mother of the resulting race, it seemed to him only right.

The Treatment of Fractures.—Sir Anthony Bowlby, the president of the British Royal Society of Medicine, at a meeting of the clinical section of that body, held on January 9, 1920, spoke on the application of war methods to civil practice. With regard to the treatment of patients with fractures, he said that the fractures in France during the last year of the war were treated by "extension and suspension," so that the circulation and mobility of the injured limb were maintained throughout as far as possible, and wasting of muscles and stiffness of joints had been thereby largely prevented. All hospitals and medical schools should arrange for much more systematic teaching of how to deal with fractured limbs, so that all young surgeons would in future realize that the so-called "setting" of the fracture was the beginning and not the end of surgical treatment. It would be necessary, therefore, for some at least of the fracture cases in general hospitals to be collected in special fracture wards equipped with the necessary apparatus for extension and suspension and supplied also with a mobile *x*-ray outfit, for there were many cases in which a good result could be obtained only through the knowledge imparted by frequent radiography.

1. **Prostatism.**—Edward L. Keyes, Jr., describing prostatism as the condition which results from obstruction to urination at the bladder neck due to adenomatous or sclerotic changes in the glands of the prostate itself, or of the posterior urethra, and discussing the various pathological changes which lead to this condition, considers the treatment under the two heads, *when to operate*, and *what type of operation should be employed*. The prolonged preparation of the patient for operation upon the prostate and the prolonged and careful after-treatment constitute an orderly systematized medical procedure. But the operation itself remains a blind, bloody, brutal, blundering performance —an emergency operation, if ever there was one. Such being the case, it is small wonder that a very large proportion of physicians and public still look askance upon the operation, and refuse to submit to its dangers, seeking rather the relief afforded by the catheter. It is probably still the case, as has often been alleged, that in a cross section of the community the general surgeon or practitioner will promptly dispose of about forty or fifty per cent. of the operable prostatics who seek his assistance, while the specialist will reduce this immediate mortality to about ten per cent. The answer to the question as to when a prostatic should be operated upon is that he should be operated upon just as soon as he shows symptoms of prostatism. The answer to the question regarding the type of operation involves the distinguishing of three types of cases: (1) The frankly adenomatous type with involvement of all the lobes; (2) the adenomatous type with partial involvement, one of the lateral lobes being apparently not enlarged, or with complicating sclerosis, so that one may question whether the obstruction is due to the sclerosis or to the enlargement of the lateral lobes; (3) the frankly sclerotic prostate and the adenomatous bar due to enlargement of Albarran's glands. The frankly adenomatous the writer believes to be curable by the ordinary suprapubic prostatectomy, on condition that the mucous membrane of the bladder neck is spared at the superior commissure, and that the fistula is left at a point as distant as possible from the bladder neck. The intermediate class of cases, partial hypertrophy or adenomatosclerotic cases, must be operated upon according to the same principle. The problem of the frankly sclerotic prostate is still with us. Various types of operation have been devised, any of which will temporarily relieve a certain proportion of cases. The writer knows no universal answer to the question of the best operation for this type of cases.

5. Hemostasis Obtained with Small Rubber Bands Instead of Ligatures.—Angelo L. Soresi has found the use of small rubber bands very satisfactory in obtaining hemostasis or for tying tissues, and recommends them instead of ligatures. The bands, one or more on each, are placed on the artery forceps, at the hinge, the forceps then being boiled, care being taken not to boil them long enough to impair the resiliency of the rubber. When the tissues or the blood vessel are caught in the usual way with the forceps, a band is slipped over the tissues or vessel with the help of the thumb forceps, and the artery forceps are immediately removed. The bands make possible the safest hemostasis because there is no danger of late hemorrhage due to the slipping of the ligature, the unraveling of knots, or the cutting of the tissues by the ligature itself. The rubber band grasps the tissues immediately and securely, at the same time it does not stop the flow of blood to the tissues by a violent strangulation, as happens when the ligature is used. The resiliency of the band prevents its cutting the tissues. The band cannot slip when it is being placed over the tissues, as it must pass from the artery forceps which hold the tissues before the forceps can be removed. As soon as the band passes beyond the tips of the forceps blades the tissues are securely held, the band forming a groove out of which it cannot slip. The application is much more rapid than that of the ligature. The rubber, when pure, is tolerated by the tissues better than is catgut, silk, or any other material now used for ligatures, and also because, being free from knots and ends, it leaves less foreign material in the wound. The band, furthermore, is safer because it avoids the possibility inherent in all ligatures of having the ends act as setons. The danger of infection is less because the bands, unlike the ligatures, are never touched by the hand. Because of the gentle action of the rubber band in compressing the tissues, the tissues beyond the band are not condemned to rapid death and sloughing. In the abdominal cavity this is important with respect to the danger of infection and the formation of adhesions. The cheapness of the bands is another item of advantage. The writer has used the bands on tissues and rather large blood vessels, being unable to find on the market bands small enough for small blood vessels. In some cases he has doubled the band, but prefers a single band proportionate to the vessel or tissues to which it is to be applied.

1. The Clinical Rôle of the Fat-Soluble Vitamin: Its Relation to Rickets.—Hess and Unger, referring to the large amount of study which, in the last few years, has been devoted to the deficiency diseases, especially scurvy, call attention to the fact that these investigations have brought forward results that coincide remarkably for animals and for man. All diets leading to scurvy in the guinea pig produce scurvy in man; all antiscorbutics are potent for both species; all signs and symptoms of the disease are common in some degree to both guinea pig and man. There is, however, the important difference that in man the disorder is a slow, markedly subacute process, whereas in the guinea pig it is almost an acute disease. An investigation of scurvy naturally led to a consideration of rickets, a disorder which, from a clinical standpoint, has always been linked with scurvy. Of the numerous theories as to the pathogenesis and etiology that of the vitamin deficiency is the newest. The present status of the etiology is briefly reviewed. The subject of rickets can be well studied on infants, owing to its great prevalence, but no systematic study of a group of infants carried through a long period has been made so far as the writers are aware. This is due in part to the fact that an investigation of this kind is impossible in the hospital, in the dispensary, or in the home, but can be carried out only in an institution where the hygienic and sociological conditions are alike for the entire group, and where all factors are under absolute control. About a year and a half ago they undertook the study of rickets in about 100 infants cared for in a modern child-caring institution. These infants lived under excellent hygienic conditions, their nursing care was the same, their food was prepared in a central diet kitchen, and they remained in the institution for the entire period of observation. Once a month they were examined for rickets. This included notation as to the size of the fontanelle, the beading of the ribs, the enlargement of the epiphyses, the condition of the musculature, the eruption of the teeth, the static development, etc. They were placed on various diets—an abundance of fat and fat-soluble vitamin in the form of milk and cream; a deficiency of these substances, as in skimmed milk; an abundance of water-soluble vitamin as supplied by autolyzed yeast; or diets such as Mellin's Food or condensed milk. In all cases there was but one deficiency in the diet, which was adequate in quantity, that is to say, in its caloric content, and contained in every instance sufficient antiscorbutic foodstuff. After a preliminary study it seemed that beading of the ribs, especially in conjunction with enlargement of the epiphyses, furnished the most reliable criterion of the course of the disease. They turned, therefore, to an intensive study of the ribs. It was found that six grades of beading could be distinguished. If the examinations were carried out always by the same person remarkable uniformity could be obtained. The writers discuss the significance of beading, and chart their findings, calling attention to the fact that there was not only rachitic, but also scorbutic beading. This conforms to observations in experimental scurvy. Turning to the question of the influence of fat-soluble vitamin in the etiology of rickets, the writers call attention to the well known fact that this vitamin is present in abundance in animal fats—such as cream, butter, and eggs—as well as in the leafy vegetables, but absent or almost absent in the vegetable oils. As far as has been demonstrated it cannot be synthesized by the animal body. In order to provide an adequate amount of this important dietetic factor they placed a number of infants, during the first months of their lives, on large amounts of milk, in some instances giving cream in addition. By this means, if fat-soluble vitamin is the controlling influence, the development of rickets should have been prevented. In some cases, with this dietary, which also included orange juice, a very mild degree of rickets was observed, but in others marked signs developed. Rickets developed in several instances on 24 ounces daily of protein milk (containing about 2.5 per cent. of fat) and even in nursing infants, whose mothers were on a diet that included a large quota of milk, butter, and vegetables. It is difficult to bring these observations into harmony with the hypothesis of a lack of fat-soluble vitamin. This point is discussed *pro* and *con*. Approaching the question from the other side—whether infants who receive very little fat-soluble vitamin in their diets become rachitic—five infants were put on a dietary that was complete in every respect except for a lack of this principle. The babies were from four to nine months of age, and somewhat below the average in physical development. They should have developed rickets if a lack of fat-soluble vitamin is the essential cause of this disorder. The results, which are given in charts, show that this vitamin is not the much sought for antirachitic factor; that it cannot bear the same direct relationship to this disorder as do other vitamins to their respective diseases—referring to scurvy and beriberi. Even if rickets is in

some degree influenced by a fat-soluble vitamin deficiency there are more important and dominating factors that determine whether or not the disorder shall come to pass.

4. A German Bullet Embolus.—H. J. B. Fry reports a remarkable instance of the migration of a rifle bullet in the venous blood stream. There was a small oval wound of entry a half-inch below the left anterior superior iliac spine. The bullet entered the vascular system by gouging the posterior aspect of the left external iliac artery and penetrating the lumen of the left internal iliac vein, causing an arteriorvenous aneurysm of these vessels. From this position the bullet was carried up the common iliac vein and the inferior vena cava. It passed through the chambers of the right side of the heart, through the pulmonary valve into the left branch of the pulmonary artery, where it impacted as an embolus in one of the branches supplying the lower lobe of the left lung, thereby causing two infarcts in this lobe. Such a tortuous and deflected course is in itself remarkable, but, in addition, there was no injury to be found in either of the veins along which it traveled or of the flaps of the tricuspid and pulmonary valves through which it passed. Moreover, there was never any pain or discomfort referred to the heart or the lungs. The question naturally arises whether this bullet could have found its billet by any other path. The clinical evidence and post-mortem findings prove without question that the bullet could only have reached its final situation by the above route, as there was no other wound of the body and no other place of entry into the vascular system except the above-mentioned aneurysm.

6. Rhinoplasty and Cheiloplasty. Rushton Parker.

5. The Significance of the Position of a "Contraction Ring" in Cases of Extreme Pelvic Contraction with Vertex Presentation.—C. D. Lochrane holds that in obstructed labor due to contracted pelvis with a vertex presentation it is at least doubtful if a true "retraction" (Bandl) ring can form before sufficient upper uterine segment retraction has occurred to elevate the site of the ring above the level of the fetal shoulders. But cases are occasionally seen in which the formation of a "ring" has become so marked before this stage that it is found constricting the fetal neck more or less closely. The trunk and limbs of the fetus are then imprisoned above the ring in an unretracted, but often apparently tonically contracted, upper uterine segment. With a markedly contracted pelvis, the head, in these cases, is held in purchase between the ring above and the pelvic brim below. The most recent view is that a "ring" formation in this position under these circumstances does not merit the name of "retraction ring" (Bandl), but is rather of the nature of a "contraction ring" due to local spasm of the uterine muscle (with or without contraction—but without definite marked retraction—of the upper uterine segment). In the opinion of the adherents of this view the chief cause of this spasm, before marked retraction has taken place, is overirritation of the uterus by excessive manipulations in efforts to deliver. Though opinion is not even now unanimous on this point, there is undoubtedly much to be said in its favor. Whatever the exact pathogenesis of the ring may be in these circumstances a very serious proposition is undoubtedly encountered when it develops in association with a markedly contracted pelvis. Lochrane has had the opportunity of treating one case of this type and of observing the treatment of another. In both the conjugate diameter was so small that the indication was absolute for cesarean section, had the cases been seen at or before the onset of labor. There had, however, been much intrauterine manipulation in both during previous attempts to deliver. A ring in both cases tightly constricted the fetal neck (vertex presenting). It appeared quite impossible that the head could be delivered upward through the ring if cesarean delivery were attempted. It appeared equally certain that, even were it possible to deliver the head *per vias naturales*, it would have been quite unsafe to attempt extraction of the trunk through the narrow ring, however extensive the previous embryulcia. In the writer's case the upper uterine segment showed some evidence of thickening above the ring as compared with the part below, the fetal trunk being somewhat difficult to palpate distinctly. The ring sulcus was quite marked on external palpation, and indeed to the eye. In such cases an unusually difficult situation is presented, the fetal head being absolutely fixed and impacted between the "ring" above and the true brim below. By the time the case reaches this stage the fetus is usually dead, owing to the cutting off of the maternal blood supply—the result of tonic uterine contraction. In considering the treatment of this condition it must be remembered that, while the usual death of the fetus gives the widest latitude in choice of procedure, the patient is generally in rather bad shape physically. There is danger in extensive or prolonged manipulations both of general collapse and of uterine rupture. The type of interference involving the least shock, and that capable of being performed most rapidly, is that to be chosen. The lines of treatment calling for consideration are: (1) craniotomy alone; (2) craniotomy with embryulcia; (3) cesarean section alone; (4) cesarean section after craniotomy; (5) cesarean section after craniotomy and decapitation. The best choice for the patient lies between craniotomy followed by cesarean section and craniotomy *plus* decapitation and cesarean section. Preliminary craniotomy should be done in any case. In the unlikely event of the fetus being alive, an effort must be made to save it, even at added risk to the mother. Under suitable conditions immediate abdominal cesarean section, with rapid incision of the ring internally, would be the correct treatment. The site of incision being under immediate control, the choice of the immediate suture or hysterectomy would then be guided by the probability of previous septic infection. In the writer's case the abdominal cesarean section, under deep chloroform anesthesia, was performed, and supravaginal hysterectomy was done, both adnexa being left *in situ*.

Influenza in Fiction.—According to Posthuma, Maurus Jokai composed late in the nineteenth century a novel which appeared in English in 1901 with the title, "The Nameless Castle." The scenes are laid in Hungary in 1809. A character receives a letter from a locality in which influenza prevails, or may prevail, and is advised to disinfect it with burning camphor. Asked to explain, the adviser states that Napoleon brought the disease home from the battleground of Eylau, and it became necessary to erect a hospital in Paris for the care of victims who were severely smitten. The comment is made that influenza is harmless in its native soil, but transported to a new locality becomes a deadly pestilence. This description fits the recent pandemic better than the disease of 1890, which Jokai doubtless witnessed.—*Nederlandsch Tijdschrift voor Geneeskunde.*

Society Reports.

WESTERN SURGICAL ASSOCIATION.

Twenty-Ninth Annual Meeting, Held at Kansas City, Mo., December 5 and 6, 1919.

THE PRESIDENT, DR. ROLAND HILL, ST. LOUIS, MO., IN THE CHAIR.

Artificial Impaction of the Femur in the Aged.—Dr. CHARLES D. LOCKWOOD of Pasadena, Cal., said that the frequent occurrence of nonunion in fractures of the neck of the femur, not only in the aged but also in young adults, was chiefly due to peculiarities of circulation in this location. The blood supply of the neck of the femur was different from that in the shaft of the bone. The more accurate the approximation of the fragments in fractures, the less exudate and callus there would be, and the more rapid the healing process. Failure of bony contact would often cause nonunion in the long bones at any age; it was almost sure to result in non-union in the neck of the femur in old people. Artificial impaction was an essential part of the treatment as demonstrated by Cotton. It afforded immediate bony contact and insured an adequate blood supply for union. With the patient under anesthesia, the limb was placed in extreme abduction and strong traction with slight internal rotation applied. The great trochanter protected by two layers of felt, was struck three or four swinging blows with a large wooden mallet. A light plaster of Paris cast was applied from below the knee to the waist line and including the sound limb to the knee. The anesthesia lasted only five or ten minutes, and there was no shock to the patient. The patient was placed upon a fracture bed equipped with a special frame and elevating device, enabling the nurse to raise the patient with ease, to bathe, attend to the bowels, and change the bedding. The cast might be removed as early as the eighth week, but if well borne, it should be left on for twelve weeks. By the end of the fourth month the patient was up and about on crutches and bearing some weight on the broken leg. The speaker had treated three fractures successfully by this method in people over 70 years of age, and all were walking and perfectly well.

Some Rarer Fractures.—Dr. EDWARD EVANS of La Crosse, Wis., read a paper of which the following were the conclusions: (1) Industrial injuries and employment liability insurance acts of various states have shown that it is indispensable to take *x*-rays of injuries involving hands or feet, if any suggestion whatever of crushing or sprain exists, as fracture of the small bones of the hands and feet are very frequent, often have very little displacement, and are frequently overlooked unless the *x*-ray is used. (2) Fractures of the bones of the hands and feet require careful and sufficiently prolonged immobilization, after careful reposition, if there is displacement, to get good results. (3) It is rather hard to get and maintain exact apposition of fractures and prevent overlapping of fractures of the long bones. (4) It is not certain if open reposition under favorable conditions—proper surgical and hospital facilities—should not be resorted to more frequently. (5) While the war has helped to stimulate a much needed closer study and interest in the treatment of fractures, it is doubtful if we have learned much that is applicable, or at least has yet been applied in our practice. (6) No satisfactory explanation has apparently as yet been made for the rarefaction of the bone leading to pathological fracture, no fundamental cause or causes sufficient to explain this condition.

Surgical Experience with Tuberculosis of the Joints; Rollier's Heliotherapy.—Dr. GUSTAV SCHWYZER of Minneapolis, Minn., stated that it was his practice to operate on every tuberculous joint under an Esmarch bandage whenever it was feasible. Only with this bloodless procedure was he able to differentiate between healthy and diseased tissues. As to the method of operating, he generally followed the method of Kocher. Through his incisions free access could be gained to the entire diseased area, and it was very important that all tuberculous tissue be carefully excised. If the disease was confined purely to the synovial membrane of the joint, he limited his work entirely to the removal of this membrane, thus avoiding complete ankylosis. But if the bone was involved, the bone ends were exposed by dislocation. The healthy outer integuments were stripped up and turned back like the cuff of a sleeve. Then the diseased part of the bone was cleanly removed. If one aimed at a complete ankylosis, a good apposition of the bones was imperative. In all resections the wound cavities were drained with rubber tubes surrounded by washed-out iodoform gauze strips. The buried suture material consisted of silk and linen. Silkworm gut was the best material for the surface. A plaster of Paris cast was put on before the Esmarch bandage was released. The drains were removed through windows in the cast within a week. As to Rollier's treatment, it would be taking another great step ahead in the treatment of surgical tuberculosis if we could establish numerous institutions in America where this treatment could be used intelligently; but not having the benefit of such institutions at present, we must face the situation as it lay before us. Granted we had the advantages of hospitals specializing in heliotherapy, there would always be patients who could not spend a year and a half to three years in such institutions, waiting for a definite cure. For these patients surgery might be preferable.

A Mixture of Ethyl Chloride, Chloroform, and Ether for General Anesthesia; an Experience in War Surgery.—Dr. E. P. QUAIN of Bismarck, N. D., said that the observations that were made in the use of this mixture in the type of surgery which confronted the medical officer at the time were very favorable. It was uniformly considered the most suitable anesthetic for most minor injuries as well as for wounds of moderate severity. It was employed at Evacuation Hospital No. 114 in the Argonne during the last part of the war as the anesthetic of choice for most operations which could be finished within fifteen or twenty minutes. The speed of the operating team was, therefore, in many instances, the criterion as to whether the choice would be the ethyl chloride mixture or simply ether. Ethyl chloride was put into the bottle from a tube up to the 5 c.c. mark, 1 c.c. chloroform was added, lastly ether was poured in up to the 30 c.c. mark and the liquid was thoroughly mixed. *Method of Administration.* (1) One of two pieces of cotton flannel was laid dry over the patient's face and the other piece was placed in a cup or small pus basin. (2) The whole content of the bottle was poured into the cup over the piece of flannel, which absorbed practically all of the 30 c.c. mixture. (3) The piece of flannel was then rapidly picked up before evaporation took place and spread out smoothly over the other piece on the patient's face. The patient must be told to hold his breath before the saturated cloth was approximated to the face and until the mask was properly adjusted. (4) The mask was placed over the face and the puckering string drawn tightly and tied so that the margin of the mask was held firmly around the face, under the chin, in front of the ears, and over the top of the head. It was desirable that the mask be applied air tight to the face, although practically this might be impossible, especially over the hairy part of the head. There could be no reason why this ethyl chloride mixture should not be used in emergency surgery in civil practice when conditions and necessities corresponded more or less to those of the wounded soldiers.

Operative Technique in Spina Bifida.—Dr. JOSEPH RILUS EASTMAN of Indianapolis, Ind., presented a communication in which he formulated the following conclusions: "(1) Spina bifida associated with increasing hydrocephalus is inoperable. (2) Spina bifida associated with paralysis should be operated on only for the purpose of preventing subsequent ulceration and rupture. (3) Rubber dam, stitched at one margin to the skin below the tumor, adhesive plaster, and plentiful collodion should be used to prevent fecal and urinary contamination. (4) A light, rubber-covered clamp applied to the neck of the tumor is the safest method of preventing the loss of cerebrospinal fluid, and also of excluding infection from the cord. (5) The sac can usually be tied off as in inguinal hernia."

Rhinophyma.—Dr. M. G. SEELIG of St. Louis, Mo., said that rhinophyma was an essential disease of the nose of more than ordinary interest. Rhino-

phyma might be described fairly accurately if one merely set down the various descriptive terms which had been used in naming the disease, such as whiskey nose, pound nose, nodular nose, growing nose, copper nose, elephantiasis of the nose, hypertrophy of the nose, lymphangioma, acne hyperplastica, fibroma molluscum, and cystadenofibroma. In the earliest stage of the disease the nose was a dark copper red, and there were dark red spots about it, particularly on the cheeks and at the glabella. Gradually there appeared on the nose lentil-size to pea-size discrete or confluent nodules. As these nodules coalesced, and the soft parts hypertrophied, the whole organ became deformed by the tumor-like nodules. The deformed growths occurred usually at the tip and on both alæ, and might be discrete and lobulated, or they might fuse, forming one large knob. Sometimes they were pedunculated. The disease occurred usually in the fifth and sixth decades, that is, the deformity was complete at these periods, the process having taken five to twenty years to develop fully. The treatment of the disease was exclusively operative. The most satisfactory operative procedure consisted in shaving off the redundant tissue until the nose was brought back to what one assumed was its original form. In this shaving process, two things should be borne carefully in mind: (1) Do not shave too deeply. (2) Preserve a thin rim of epithelium around the nares. If the shaving was carried too deeply, all sebaceous gland rests were removed and no niduses of epithelium from which, as brood centers, epithelization might spread, were left. This delayed healing, and even if the nose were grafted, the resultant skin had a harsh, white, dry appearance so striking as always to attract attention and cause comment. Furthermore, deep shaving might injure the nasal cartilages and set up a stubborn perichondritis. If a thin ring of intact skin was not left around the nares, serious disfigurement might result from the contractions incident to cicatrization. Hemorrhage, which was usually very free, was checked with comparative ease by simple gauze pressure, and the patient was sent to bed with a large, well vaselined gauze pad over his nose. The next day this pad was removed, and the denuded area was strapped with imbricated strips of sterile zinc oxide adhesive plaster. This plaster dressing was changed daily. It was not necessary to skin graft these patients.

Diaphragmatic Hernia.—Dr. T. F. RIGGS of Pierre, S. D., said that according to Giffin, about 650 cases of diaphragmatic hernia had been reported in the literature up to 1912, and 18 articles on this subject, from the point of view of the radiologist or surgeon, had appeared during the past two years. According to the authorities, the great majority of the diaphragmatic hernias occurred to the left of the midline. The case reported by him he believed to have been a true traumatic hernia on the right of the median line. If it were true that the profession was not making as high a percentage of correct diagnoses in diaphragmatic hernia as in other more frequent abdominal conditions, the failure was probably due to lack of a sufficiently definite symptomatology. It was reasonable to expect the traumatic hernia to be more easily diagnosed than the nontraumatic form, but one must remember that the severity of the symptoms was not necessarily in keeping with the size of the hernia. The possibility of a diaphragmatic hernia should be more often considered.

Jaundice and Its Surgical Significance.—Dr. CHARLES H. MAYO of Rochester, Minn., stated that jaundice as a symptom of disease might present a very serious problem in tracing its cause. In approximately 50 per cent. of the cases seen the absorption of bile was due to obstruction of the common duct by gallstones; in 20 per cent. of all cases it was due to absorption of bile in the liver, or infective or catarrhal jaundice without duct obstruction. From 5 to 8 per cent. of cases of jaundice were due to serious infection of the gall-bladder, possibly gangrene with or without stones. They were usually accompanied by a degree of pancreatitis with marked swelling of the lymph glands on the three ducts; all persons having one on each duct, but no one more than two. Jaundice from cancer presented a very serious problem, although it represented but 15 per cent. of the cases seen; one-half of these were from cancer of the liver, the other half from cancer of the pancreas, or the gall-bladder and ducts. During the years 1916, 1917, and 1918, in thirteen cases seen it was necessary to unite the hepatic duct either to the duodenum or to the stomach; two of the patients died. Jaundice was a late symptom of gallstones in the majority of cases, the result of neglect to recognize the condition or to advise operation in the preventive period. The mortality following cholecystectomy in the treatment of cholecystitis with or without stones was low, only 1.8 per cent. in 2,460 operations performed during a period of three years. There were 337 cases in which the cholecystectomy and choledochotomy were both done with a mortality of 3.2 per cent. In a very serious group of thirty-six cases of obstruction and malignancy, cholecystostomy and choledochotomy were done with a mortality of 16.6 per cent. Choledochotomy alone was done in a somewhat similar group of forty-seven cases, with a mortality of 15 per cent. If all the choledochotomies were grouped together, however, the mortality in the 420 cases was but 5.7 per cent., too high a mortality for simple cases of stone and obstruction, and too low for the late and complicated cases, including the cancers. Stones were found in the common duct in 274 of the 420 cases.

A Congenital Anomaly of the Duodenum and Its Surgical Significance.—Dr. LEONARD FREEMAN of Denver, Col., said the surgical treatment might be difficult because of certain more or less awkward complications. (1) The lesion was deeply situated, being due to a firm adhesion pulling the gut down to the root of the colonic mesentery, the embarrassment often being further increased by the location of the incision, which was usually to the right of the spine, while the kink was to the left. (2) The inferior mesenteric vein and left colic artery lay just external to the kink and might be injured if care was not exercised; hence, one should cautiously strip the peritoneum bluntly from the surface of the bowel, rather than attempt to divide the ligament with knife or scissors, taking care that the gut was not perforated during the manipulation. (3) The completion of the procedure exposed a raw intestinal surface which might be quite large, and required attention in order to prevent troublesome adhesions. Sometimes the edges of the torn peritoneum could be stitched together so as to cover the denuded area without compromising the lumen of the bowel, but occasionally it might be desirable to employ a free omental graft, as he had done in one instance. Since his attention had been called to this subject, he had operated upon six of these duodenal obstructions. In no one of them was the diagnosis made previous to the operation, the real trouble being discovered only after a lesion near the pylorus had been excluded. Partial occlusion of the duodenum at the duodenojejunal angle, simulating pyloric obstruction, occasionally occurred from the persistence of a condition normally existing in fetal life. In this, the duodenum, instead of appearing in the abdominal cavity from beneath the transverse mesocolon to the left of the spine, as it should, emerged to the right, its transverse and ascending portions possessing a peritoneal covering and mesentery of their own, similar to the rest of the small intestine, instead of being fixed in fibrous tissue, as was normally the case. At the duodenojejunal angle, however, the bowel was hung up to the root of the colonic mesentery by a firm adhesion, the kink thus produced being intensified by the downward pull of the free duodenal loop. This kink was deeply situated and in freeing it care must be taken not to injure the bowel, the inferior mesenteric veins, or the left colic artery. A considerable denudation of the gut might be necessary, which should be covered either by reuniting the peritoneum or by means of a free omental graft.

Abdominal Drainage.—Dr. D. W. BASHAM of Wichita, Kan., took the ground, in this paper, that we should avoid indiscriminate drainage. The drain should be placed in a careful manner so as to conduct the products of infection away from the field of operation to the outside of the abdomen. All sorts of manipulations of the abdomen for the purpose of facilitating the outward flow of pus should be avoided. When the drain had completed its function, it should be removed, and one should not try to replace it; especially the remaining sinus should not be plugged up with gauze which

could serve but to obstruct the escape of the serous flow which must follow.

The Surgical Treatment of Empyema.—Dr. W. W. GRANT of Denver, Col., confined his remarks to his personal experience based upon the two epidemics of 1917-18 and 1918-19, at the Recruiting Depot, Fort Logan, Col. In the epidemic of 1917 and spring of 1918, he operated on twenty-eight cases of empyema, with a mortality of six cases, and in the winter of 1918 and 1919, he operated on three cases only with no mortality. There were 300 or 400 cases of influenza and as many cases of pneumonia as in the former epidemic, but it was much more fatal and fewer cases reached the surgeon for operation. A detailed report of twenty-eight cases was made to the Surgeon-General's Office. In all cases, twenty minutes before the operation, an ounce of whiskey was administered and a hypodermic injection of 1/6 grain morphine with 1/200 grain of atropine and ½ grain of spartein. One to one and a half inches of rib were resected. On the right side the eighth rib and on the left the ninth or tenth, usually in the posterior axillary line, the aim being to secure the most dependent drainage. A rubber drainage tube, sometimes double, was immediately introduced and the tissues sutured snugly around it, the tube fixed primarily with a stitch and a safety pin, and the long outer tube dropped into a bottle of water beneath the bed as in certain cases of gall-bladder drainage. The quantity of pus varied from two to four quarts. The discharge diminished rapidly, and on the second or third day the patients were taken to the dressing room twice daily and the cavity irrigated with a 5 per cent. bicarbonate of soda solution, adding boric acid and immediately followed by a solution of iodine. The shortest period in which any patient returned to duty after operation was seventeen days, while the convalescent period with most was from two to three months. Empyema was not cured by aspiration nor by the immediate closure of the wound after operation. It was recognized that in the influenza and pneumonia epidemics the character of the infection was more intense and varied, and the mortality in consequence greater under any treatment than we had been accustomed to experience in sporadic cases under ordinary conditions of life.

Malignant and Benign Tumors of the Breast.—Dr. BYRON B. DAVIS of Omaha, Neb., said that his private records of operation for diseases of the breast contained the histories of 166 persons suffering from malignant tumors, and 44 from benign. In this series no cases had been included that were operated on during the last three years, and the records covered his private work from 1898 to December, 1916. The records of many other cases operated on were inaccessible or so incomplete as to be valueless. The cases included had practically all of them been verified by the microscope in the hands of a trained pathologist. Of the 166 cases of malignant disease that an effort had been made to trace, there was one operative death, the remaining 165 having left the hospital apparently in good condition; 165 were diagnosed as carcinoma, and only one sarcoma was found. All but one occurred in women. His study of these cases and the results obtained were encouraging rather than discouraging. Operations for cancer saved lives. The very early operation, so early that the microscope was necessary to make the diagnosis, was bound to produce better results than the operation done after the disease was easily diagnosed. The radical operation should be directed in such a way as to remove as thoroughly as possible the highways along which the disease was disseminated. The campaign of education of the public with reference to the signs of early cancer and its curability, when operated on early, should be continued and kept up unceasingly. Finally, the fact should be appreciated that every woman operated on for cancer of the breast, who remained free of the disease, afforded a basis for more powerful propaganda in the community in which she lived than all the tracts that could be written.

Cancer Involving the Mouth.—Dr. GEORGE NOBLE KREIDER of Springfield, Ill., read this paper. He held that the radiograms of the chest should be included in every case of preliminary examination of patients showing evidences of cancer in the mouth or breast. This had been his invariable procedure for the last two years. Many times such conditions would be found in the chest picture as would cause the surgeon to hesitate to operate. In several of his cases the patients had insisted on operations even though it was explained that there was little hope. Cancer involving the mouth had always seemed to him to be the most frightful form of malignant disease. When the disease attacked other parts of the body, the patient might have considerable periods of mental and physical relief. But in the mouth, and especially when the tongue was affected, there were few moments of the waking hours that were devoid of pain and mental distress. These cases, therefore, deserved particular study. Between April and October, 1919, four mouth cases came under his observation. The first man appeared May 19. The patient was still living, but his condition in August was reported very bad. The right upper maxilla was involved. The tongue was involved in the second man, who appeared April 9. He died June 29, surviving 80 days. The third man appeared June 17, and died December 10, surviving 168 days. The fourth man appeared August 6, and died September 21, surviving 45 days. In civilized countries, the disease was much more frequent in men than in women. The teeth were found diseased and irritated the growth in every case. The teeth should always be removed before any treatment was attempted. The men, without exception, had been large consumers of alcohol. They were also excessive users of tobacco. Some day the profession and people would wake up to the dangers of nicotine poisoning. It was not possible to operate on any of these patients because the disease was too far advanced.

The Operative Treatment of Vesicovaginal Fistulas.—Dr. E. S. JUDD of Rochester, Minn., stated that in former years vesicovaginal fistulas were found for the most part after difficult parturition. At present they occurred frequently from procedures for the radical removal of carcinoma of the cervix uteri, whether by operation, cautery, or radium. Sixty-one per cent. of cases of vesicovaginal fistula operated on at the Mayo Clinic since 1908 had resulted from some operative procedure for the removal of tumors of the uterus; and only 39 per cent. followed childbirth. Of five cases in the above series the fistulas followed the use of radium alone. Radium was of undoubted value in inoperable carcinoma of the cervix, but should not be used if the tumor had not been removed or if fistulas remained. The scar resulting from the cautery and radium rendered the technique of the operation much more difficult than in the cases which followed childbirth. The first essential in the treatment consisted in destroying the communication between the vagina and the bladder and the best manner of accomplishing this was to dissect the bladder completely away from the vagina as was done in the operation for the relief of cystocele. If the mucous membrane of the fistulous tract was not freed so that it could be turned into the bladder on the one side and into the vagina on the other, the communication would almost certainly reform. Undoubtedly a certain percentage of these patients required more than one operation and repeated attempts should be advised to close the fistula, if the sphincter muscle of the bladder had not been destroyed. If the sphincter muscle was injured it should be repaired and the fistula closed. If it was impossible to secure function of the sphincter a communication between the vagina and rectum just above the anal sphincter could be made and the vaginal outlet closed. This procedure as advocated by Keen was probably the best in these unfortunate cases. Peterson collected forty-one cases in which this operation was performed with comparative success. Seventy-eight cases of vesicovaginal fistula had been operated on in the clinic since 1908. In fifty-four of these it was possible to close the fistula with one operation, in sixteen, two operations were performed, and in one six operations failed completely to close the fistula. The size of the fistulous opening in these cases varied from that of a small pin point to complete eversion and prolapse of the bladder. In three of the cases there was more than one opening. A large incision in the vaginal wall included all the openings and converted the operation into a single closure after the openings into the bladder had been separately closed. The bladder sphincter was involved in ten cases, but it was destroyed in only three; it was repaired quite satisfactorily in

the seven cases. One of the ureters was involved with the vesical fistula in six cases. The position of the ureter should always be determined and in some cases where it was involved in the fistula the suprapubic operation was the one of choice. Legueu had recently advocated the transperitoneal vesical route for vesicovaginal fistula. This operation had some advantages in the cases in which the fistulous tract became attached to the pubic bone and was thus held in a most inaccessible position for the vaginal route. If the fistulous opening was small the fistula might be inverted into the bladder and held there by tension on the pursestring suture which was pulled out through the urethra. This procedure was described by C. H. Mayo. A number of small vesicovaginal fistulas had been closed by the high frequency current. Before operation the tissues should be made as near normal as possible. A cystoscopic examination should be performed to determine the position of the ureters, the presence or absence of a sphincter muscle, and whether or not the bladder had been completely severed from the urethra. When the injury was near the neck of the bladder, the vaginal operation was the one of choice. When the opening was high in the vaginal fornix and there was much scar tissue, the suprapubic operation might be of service but more room might be secured for the vaginal exposure by incision of the perineum. A long incision was made in the vaginal wall down to the bladder, beginning below the sphincter muscle and extending to and through the fistulous opening. The bladder was then separated from the vagina, beginning near the cervix and bringing it forward toward the urethra. If the cervix had been removed and the fistula was high in the vagina the peritoneum might be opened, as advocated by Kelly. A small curved hemostat passed through the urethra and into the vagina through the fistula helped to bring the fistulous tract downward into the dissection. After the bladder had been loosened and its edges could be easily approximated the opening should be closed with catgut and the edges of the mucous membrane inverted. The vaginal incision might then be closed with chromic catgut and all dead space obliterated. If the sphincter had been repaired it was best to use fine silk sutures in addition to the catgut, being careful not to penetrate the mucous membrane with the silk. A retention catheter was left in the bladder for from eight to ten days. The patient should be kept quiet for from twelve days to two weeks. There was no mortality in this series. Of fifty-six patients heard from, four had derived no benefit from the operation: six were considerably improved, and the remaining forty-six were completely relieved.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held November 18, 1919.

DR. EDMUND P. SHELBY IN THE CHAIR.

Influenza and Tuberculosis.—Dr. MAURICE FISHBERG presented this paper in which he stated that during the past two years the menace of influenza had loomed up as important not only as an acute and deadly disease, but also as a pathological process which was likely to increase the morbidity and mortality from tuberculosis for years after it had abated or disappeared. This was seemingly in agreement with our present view of phthisiogenesis that pulmonary tuberculosis was in most cases a reactivation of an infection with tubercle bacilli acquired many years before the onset of active symptoms, and that hardly any one escaped such infection before reaching adolescence. It had been stated that when a patient with active pulmonary phthisis was attacked by influenza, the tuberculous process in the lungs was likely to assume a more acute and progressive course, and to terminate fatally. In other words, we had been taught that among the mixed infections to be dreaded by tuberculous patients, that with influenza bacilli was the most ominous. Influenced by these teachings, which abounded in many books and monographs on tuberculosis and on influenza, the prediction went forth that an increase in the tuberculosis morbidity and mortality might be expected during and after the recent pandemic of influenza, and the Department of Health of New York, and of other cities in this country, had issued warnings to this effect. Moreover, whenever a patient kept on coughing, or was more or less feeble during convalescence from influenza, a diagnosis of tuberculosis was likely to be made, and he was at times banished to a sanatorium or to some distant clime. That there was no basis for this apprehension was evident to the writer after the pandemic of 1918-19 reached New York City. A large proportion of tuberculous patients under treatment in this city contracted influenza, and not a single one succumbed. Some were in the far advanced stages of the disease, with large cavities in the lungs, yet they passed through the acute symptoms of influenza and recovered, the tuberculous process then pursuing its course as if no complicating disease had affected them. This was observed at the time when a large proportion of the non-tuberculous cases under the writer's care succumbed to influenza. In hospital practice experience has taught the same lesson. In fact, it appeared that the prognosis in cases of influenza was much better in those who suffered from tuberculosis, or any other chronic pulmonary disease, notably asthma, bronchitis, emphysema, bronchiectasis, etc., than in those in whom the lungs and bronchi had been apparently in healthy condition. Moreover, far from aggravating the condition of tuberculous patients, it has been observed that influenza ran a milder course than when attacking healthy persons, and the old lung lesion remained in about the same condition as could be expected if no complicating process had attacked the patient. Statistics published by some authors seemed to indicate that in from 15 to 25 per cent. of their patients the tuberculous process has been activated by influenza, or some of its congeners. But these statements of patients and statistics of physicians were vitiated by the following facts known to every observant clinician: 1. Any acute, evanescent respiratory disorder may be called "grippe," influenza, etc. Since we have learned the symptomatology and course of influenza during the past year we know that during the twenty years preceding 1918 very few of such cases could be considered influenza. Moreover, we know that acute exacerbations of tuberculous processes in the lungs were usually considered "colds" by the average patient. 2. The initial symptoms of phthisis were not unlike those of mild forms of influenza in many cases, except that acute coryza and pharyngitis were extremely rare at the onset of phthisis. If this last fact were borne in mind, and every patient who said that the tuberculous symptoms were preceded by those of influenza were asked whether there was at that time an acute rhinitis, tonsillitis, or pharyngitis, it would be discovered that nearly all would answer in the negative.

Now, this was a very important point in the differential diagnosis: Influenza, the type which had prevailed in Europe and America during the past two years, attacked primarily the upper respiratory tract, while the bronchi and lungs were affected in only a relatively small proportion of cases. The majority of patients suffered from acute coryza, tonsillitis, pharyngitis, tracheitis, etc. These inflammatory processes were practically never seen in real incipient phthisis. When, however, the lesion in influenza descends to the deeper respiratory passages, producing bronchitis, pneumonia, pleurisy, etc., confusion with acute phthisis might occur, when it was not taken into account that these symptoms were preceded and are in fact accompanied by signs of an acute inflammation of the throat. The clinical differentiation between tuberculosis and post-influenzal pulmonary sequelae was quite easy in most cases when the following points were borne in mind. Bias must be dispensed with, and if any was permitted to linger, it was in favor of the view that after an attack of epidemic influenza the lesion in the lung was unlikely to be of a tuberculous character. In phthisis the alterations in the resonance and breath sounds were almost invariably found over the upper lobe of either or both lungs, while in influenzal bronchitis, post-pneumonic fibrosis, or localized catarrh, the lesion was in the vast majority of cases found in the lower lobes, most commonly the left side of the chest. Phthisis in which such extensive lesions had developed within a comparatively short time always manifested

itself by severe constitutional symptoms, especially tachycardia, fever, emaciation, etc. In post-influenzal lung lesions the pulse was, as a rule, slow, fever was lacking, except in cases with pleural effusions, or pulmonary abscess, etc., which should be recognized by their concomitant symptoms and signs, and emaciation was exceptional. This discordance between the extent of the lung lesion and severity of constitutional symptoms should at once throw some doubt on the diagnosis of the tuberculous character of the lesion. Physical exploration of the chest also gave reliable signs as to the true nature of the disease. Percussion yielded and impaired or dull note over extensive tuberculous lesions; in many cases this was found without any adventitious sounds being audible on auscultation. The reverse was true in most cases of post-influenzal pulmonary lesions in which we frequently found a large number of coarse, consonating râles over an extensive area which is resonant on percussion. Collating available evidence, it appeared, however, that tuberculous patients were just as likely to contract influenza during an epidemic as others. But the number of severe cases, complicated by pneumonia, pleurisy, etc., as well as fatal cases, was not higher than that observed among non-tuberculous patients. Indeed, if any difference was observed it was in favor of the tuberculous. It might be stated that, after influenza had passed, the tuberculous patient remains in the condition in which we might have expected to find him had he been spared by the epidemic disease. There is neither an improvement nor an aggravation of the tuberculous lesion to be observed. Their experience in this regard is not unique. It appeared that all who had recently written on this subject report that influenza was less likely to attack tuberculous patients than others; and that when tuberculous patients were affected with influenza their outlook for survival was as good, or even better, than that of previously healthy individuals. A study of influenza in various tuberculosis sanatoria throughout the country was in accordance with the above statements, and European experience during the past two years ran in the same direction. Nowhere had it been observed that tuberculous people were more predisposed to influenza, and that when affected, the acute disease should run a more acute and fatal course than was observed in the general population. From Central and Eastern Europe available evidence shows similar conditions. Gerber was struck by the remarkably favorable course of influenza in the tuberculosis division of the No. 3 War Hospital in Vienna. From June till the middle of October, 1918, nearly two-thirds of the 750 tuberculous patients contracted influenza and only 2 of these succumbed to complicating pneumonia. In Germany, where epidemic influenza was very severe among the general population, perhaps owing to malnutrition, it was rather mild among the tuberculous. The tuberculous process in the lungs has not been observed to assume an acute and progressive course after an attack of influenza. Vital statistics and reports from sanatoriums showed that during the past and current year the mortality from tuberculosis had not increased despite the fact that influenza had been raging during this period, nor have the number of tuberculous patients seeking admission to institutions increased during the past twelve months. The pulmonary sequelæ remaining after influenza were almost without exceptions non-tuberculous in character and did not require the treatment accorded to phthisical patients.

Roentgen Ray Studies of Bronchial Function.—Dr. JESSE G. M. BULLOWA and Dr. CHARLES GOTTLIEB recorded roentgen ray observations of the bronchi of dogs in whom the tracheal-bronchial tree was outlined by barium in olive oil or petrolatum liquidum. They observed a bellows-like expansion and contraction of the bronchus, synchronous with respiration and emphasized the importance of bronchial spasm in limiting the distensibility of the lung. They also observed a longer cycle, a slow peristaltic wave of low amplitude, which emptied the lungs without cough and without invoking ciliary movement. Bechic movements were studied and the possible importance of bronchial-spasm in causing cough by traction of the parieties was suggested. The effect of adrenalin was observed and although in some lungs it caused contraction of the bronchial muscles, in others, which had been contracted by muscarine, dilatation was observed. The filling of the alveoli with bismuth was also demonstrated radiographically.

Bronchoscopic Treatment of Bronchiectasis and Pulmonary Abscess.—Dr. HENRY LOWNDES LYNAH presented this communication. (See page 215.)

Dr. L. T. LE WALD said there were several points that might be brought out bearing directly on the elimination of material that got into the trachea in esophageal fistula. Four such cases had come under his observation and he thought the Section might be interested in seeing the slides of those cases showing the fistulous tracts from the esophagus to the bronchi. In these cases the food had been going into the bronchi for some time and when this happened the bronchi seemed to develop an immunity or tolerance to food products. There was no delay in the emptying of the bronchial tree as Dr. Bullowa had described; within a day all traces of the bismuth had disappeared on *x*-ray examination of the lungs. At Bellevue College, they had injected the bronchial tree three times in the cadaver. Dr. E. W. Caldwell, in 1909, first did this by introducing fine shot into the trachea of a cadaver and then shaking them into the smaller bronchi. Subcarbonate of bismuth in suspension might be used in the study of the bronchial tree in the cadaver.

Dr. HARLOW BROOKS expressed his great admiration of the work done by Dr. Bullowa and Dr. Gottlieb. He said it opened up new possibilities in the treatment of the very difficult condition of pulmonary abscess which almost always originated from a primary bronchiectasis and in which both medical and surgical treatment had thus far been unsatisfactory. He thought that a combination of the procedure described this evening, together with the postural method employed in one of the hospitals, might be found effective. In one of the hospitals a number of cases of lung abscess were treated by requiring the patients to incline out of bed, head downward, on their hands several times a day, in the meantime coughing and expectorating. Of the cases treated in this way in this series several recovered. By adding the postural treatment to the method described it might be that the outcome would be more satisfactory in this class of cases which they all felt previously were eventually going to terminate fatally.

Dr. GEDIDE A. FRIEDMAN said he still believed asthma was due to spasm of the small bronchi and that it was possible that adrenalin caused no relaxation of the bronchi with normal tonus. Dr. Bullowa had shown that adrenalin caused contraction of the normal bronchi. The same principle held true for the pylorus. If one injected adrenalin, as he had done, in a normal human being and then made a fluoroscopic examination he would find that in the normal man, using one-half of 1-1000 adrenalin solution, nothing happened, but adrenalin immediately relaxed a pylorus that was in spasm. It seemed that adrenalin had a different action in a muscle of normal tonus from that in muscle with hypertonia. He had always found adrenalin the best remedy to relieve spasm, be it bronchial or gastro-spasm.

Dr. WILLIAM H. STEWART stated that he had had one case of esophago-tracheal fistula. It was discovered while examining the esophagus for malignancy that most of the bismuth paste passed through the fistula into the lower bronchi on both sides. They were beautifully reproduced on the roentgenograms. This patient coughed up the bismuth without any trouble although most of the cases reported developed penumonia which proved fatal. He has been interested in observing the cases of pleuro-pulmonary fistula complicating draining chronic empyemic cavities. These cases had been injected with a solution of bismuth subcarbonate in sweet oil to outline the cavities. In some instances some of the injected substance entered the bronchi through the opening into the lung without causing much distress to the patient, as it was almost immediately coughed up. He had never noticed a peristaltic action such as described by Dr. Bullowa, but, considering how rapidly these patients with pleuropulmonary fistula coughed up the bismuth solution, there could be no doubt that there was some such action aiding cough and chest contractions in expelling foreign substances from the bronchi.

Dr. EDMUND P. SHELBY said these were three very in-

portant contributions. He doubted whether the value of Dr. Fishberg's paper in which he brought out so well the relationship between influenza and tuberculosis was fully appreciated. It was very gratifying to have that subject cleared up so favorably and on the basis of such a thorough investigation, and to feel assured that influenza was not a factor in the incidence of tuberculosis. He had had several cases suspected of being tuberculous who gave a history that their trouble dated from an attack of influenza and all proved not to be cases of tuberculosis but of bronchiectasis.

Dr. ALFRED MEYER recalled that at the meeting of this Section on February 18, 1918, he had reported his experience with influenza in the tuberculous at the country branch of the Montefiore Home at Bedford. The impression that he had gained at the outbreak of the epidemic that quarantine against the disease would prove effective had been shown to be correct. Quarantine was established at the Bedford institution a few days after the outbreak of the epidemic in nearby villages, on October 6, 1918, and was continued for seven weeks and during that period not a single case of influenza developed. Lay officers had endeavored to induce him to lift the quarantine but he had remained firm and did not lift the quarantine. Finally, however, through some defect in the quarantine measures the disease gained entrance to the institution. Dr. Fishberg stated that a smaller proportion of tuberculous individuals contracted influenza than occurred among those who were free from tuberculosis. At Bedford they had 213 patients and 52 contracted influenza, about the same proportion as among the general population. They also found the mortality about the same among the tuberculous patients as among the general population. They found the age morbidity just as it was elsewhere, that was that a greater number of those under the age of forty years were affected, namely 98 per cent. of the cases were under forty years though they were only 84 per cent. of the population. The question as to what effect influenza was going to have on the further progress of tuberculosis he felt was one on which we ought to hold back our judgment for a considerable length of time. However, at the end of four months after the epidemic one of his assistants concluded from their records that there was no increase in the incidence of tuberculosis among their patients as a consequence of the intercurrent acute disease. Dr. Fishberg was to be congratulated on getting such a large amount of statistical material from so many different places. We were now in a position to say that the epidemic of influenza had had less effect upon the incidence of tuberculosis than might have been expected, *a priori*, on theoretical grounds.

Dr. THOMAS F. REILLY said the incidence of tuberculosis unquestionably was not affected by influenza this year, but it might be well to remember that influenza varied in different epidemics and that some of the salient features of this epidemic were different from those of thirty years ago. The epidemic of thirty years ago was followed by a large incidence of tuberculosis. At that time physicians did not see many of the cases with the large amount of pulmonary congestion such as were seen in the recent epidemic. It was difficult to lay down hard and fast laws for influenza that would hold good for ever and ever. The statement was made that the absolute tuberculosis mortality had been lower since the epidemic; that might be because this influenza killed off so many young people who in the nature of things would otherwise have succumbed to tuberculosis. Dr. Fishberg had also laid down as an easy problem the differential diagnosis between tuberculosis and the lung condition frequently following influenza pneumonia, but in practice it was not always so easy to differentiate the conditions. The *x*-ray was not much help in differentiating between tuberculosis and the lung conditions due to influenza. That was rather unfortunate, inasmuch as so many men depended upon the *x*-ray in making a diagnosis of tuberculosis. Most *x*-ray men acknowledged that it was impossible to differentiate the bronchial thickening following influenza from tuberculosis of the hilus. It was not so difficult to make the diagnosis when the lesion was located in the apex, but when the lesion was basal or at the hilus, it could not be so easily differentiated, and hilus tuberculosis was not so uncommon as the older textbooks might lead one to believe.

Dr. I. S. HIRSCH questioned whether any peristalsis could occur in the smaller bronchioles. He thought peristalsis might occur in a bronchiole having a diameter of one millimeter or more. The smaller secondary bronchioles had no musculature and hence were incapable of peristalsis. He thought the first action in the expulsion of fluids from the lung was that of the diaphragm and muscles of the chest wall, which forced the fluid into the bronchioles and smaller bronchi and then peristalsis, if it did occur, might force it further. He asked whether the wave of peristalsis was rapid or slow. He thought it must be rapid and would, therefore, be difficult to study in any but the major bronchi or the trachea. He asked what was the relation of the peristaltic wave to the cough. Peristalsis apparently was not a normal function, for the bronchi did not show this movement when the dog was in a natural position. The radiographic demonstration of the spasm of the bronchi and their narrowed lumen, under irritation of muscarine was interesting in connection with the work of Delafield, who believed that asthma was due to a contraction of the bronchi. He also agreed that adrenalin had no effect on the musculature of the normal pylorus or on normal bronchi, but when the muscles were in spastic contracture it then served to relieve that contraction.

Dr. MAURICE FISHBERG, in closing, said that in the paper he had not touched upon the question of quarantine, but he had paid attention to that problem. There were sanatoria which he had been able to learn of where no strict quarantine was maintained and not a single person was attacked by the disease. On the other hand, at other institutions, strong efforts were made to maintain strict quarantine but it was not entirely successful. Dr. Reilly spoke of the epidemic of 1891 as being different from the recent epidemic. A complete and reliable description of that epidemic was that of Lichtenstern, and as he described the disease it was similar to that seen during the recent epidemic. The reason they saw so much tuberculosis following the epidemic of 1891 was probably because they were not so careful in differentiating various conditions of the lungs, and any case with persistent cough was called tuberculosis. Now they were recognizing bronchiectasis, with or without the bronchoscope or the *x*-ray. It was also suggested that the reason the mortality from tuberculosis was low this year was because those that would have succumbed to tuberculosis ordinarily had this year fallen victims to influenza. With this view he could not agree. Influenza killed many between the ages of 15 and 40 years and that was the age at which tuberculosis was most common. On the other hand, if one looked at the army, notwithstanding the fact that so many had influenza, the incidence of tuberculosis was no higher than would have been expected had there been no epidemic of influenza, and it was even less, so we must conclude that so far no tuberculosis had developed as the result of influenza. He had not seen a case which could be unequivocally said to have started with influenza. It had been shown in every instance that cases that claimed to have started with influenza had shown symptoms of tuberculosis before the attack of influenza. The diagnostic problem at Montefiore Hospital had been greatly simplified following the principle that those who claimed to have been sick only since an attack of influenza last winter were not cases of tuberculosis unless tubercle bacilli were found in the sputum. And with but one exception, none of the post-influenzal pulmonary cases admitted to the Montefiore Hospital had expectorated sputum containing tubercle bacilli.

Dr. BULLOWA, in closing, said that he was happy to have seen Dr. Le Wald's pictures, as they revealed bronchial peristalsis. Dr. Friedman's remarks did not contradict their findings at all. Adrenalin did influence the contraction of muscles and the lantern slides showed relaxation from adrenalin after muscarine had been injected, though adrenalin seemed to cause contraction of the bronchi under some other conditions. The senior author was the first to recommend the injection of ad-

renalin for asthma in 1903. Hitherto our knowledge of the action of drugs on the bronchi was based on the oncometer studies of Brodie and Dixon in 1903, and this had been used also by Jackson, by Stewart, and by Januscke and Pollak. He thought this was the first time that the contraction and relaxation of the musculature of the bronchi under the influence of drugs had been visualized, and that the bronchial muscles might now be studied as the musculature of the intestines had been. Most of the animals injected a number of times were still living and apparently well after weeks. Of course animals subject to oncometer studies perished at the termination of the experiment. In reply to Dr. Hirsch, Dr. Bullowa stated that the peristaltic wave was observed in the trachea, the larger and smaller bronchi, as far as the bronchi of the second order, and it was much slower than the heart beat, but it was difficult to time by reason of the darkness, yet it was superimposed upon the respiratory cycle and independent of it.

Dr. CHARLES GOTTLIEB said that the peristaltic wave had no relation to the cough. While it was not directly upon the subject, he might mention that at Akron, Ohio, they had 400 men under absolute quarantine during the epidemic of influenza. They did not have a single case of influenza until after Thanksgiving, when the men went home on vacations; after that they had thirty cases.

SECTION ON PEDIATRICS.

Stated Meeting, Held December 11, 1919.

DR. MURRAY H. BASS IN THE CHAIR.

Some Remarks on Cranial Thrombosis in Children.—Dr. SEYMOUR OPPENHEIMER read this paper, in which he emphasized the importance of the early diagnosis of cranial thrombosis, though with the symptoms as they appeared this was often most difficult and many times impossible. In general the symptomatology of sinus thrombosis in the child was in a measure that of the condition in the adult. There were two recognized forms of sinus thrombosis—primary, or marasmic, and secondary, or infective, sometimes termed inflammatory. Marasmic thrombosis occurred much less frequently than infective, and was almost invariably located in the longitudinal, rarely in the lateral, and still more rarely in the cavernous sinus. It occurred in weakly people prostrated by exhausting disease, occurring often at the extremes of life. It was seen at times in conditions of infantile atrophy and sometimes occurred in the course of such acute infections as pneumonia, pertussis, diphtheria, and nephritis. The actual cause was a condition of lowered vitality leading to feebleness of the circulation, and an altered condition of the blood. The symptoms of marasmic sinus thrombosis unaccompanied by hemorrhage were few and uncertain in the majority of cases in which this lesion was found post mortem. The symptoms were those of meningeal and cortical irritation, and were indistinguishable from symptoms produced by more common conditions. In the chlorosis cases the head symptoms were marked as a rule. Children affected with marasmic sinus thrombosis were prone to convulsions, usually general, and accompanied by unconsciousness. The prognosis was bad in marasmic thrombosis, and the majority of cases died in a few days. In most cases the treatment was wholly symptomatic. Roborants and stimulants were indicated, and a position in bed should be assumed which was favorable to both arterial and venous circulation. The internal administration of potassium iodide and calomel had been recommended in the autochthonous forms, but no treatment was likely to prove of any avail. Secondary or infective thrombosis was much more frequent than the primary form. Its three causes might be stated as sepsis, damage to the vessel wall, and stasis. It occurred almost as frequently in children as in adults, generally affecting one of the dual sinuses, while marasmic thrombosis affected the single median or azygos sinuses. It was local in origin, secondary to some inflammatory lesion of infective character, and occurred in the sinus nearest the seat of the primary disease. By far the most frequent cause was a suppurative middle ear lesion. Sinus thrombosis affected males more frequently than females, the right lateral sinus more often than the left, probably because the right sinus was usually the larger and approximated the mastoid more closely. In infective sinus thrombosis the lateral sinus was most frequently involved. While infective sinus thrombosis might be a less frequent complication in children than in adults, a study of the statistics of institutions treating large numbers of cases of otitic disease showed that 15 per cent. occurred in children under ten years of age. The writer reviewed in a general way the gross anatomy and the pathological anatomy of the brain, directed attention to the differences between the brain anatomy of the child and the adult, and pointed out the various ways in which infection might gain entrance to the sinuses. The symptoms of sinus thrombosis were fairly constant, the most important general symptom being a rise in temperature excessively high. A perisinus abscess might cause a temperature of a very septic type. The mere presence of a high temperature in children was a less important indication for operation than in adults, but when its presence was persistent in conjunction with an acute mastoiditis and a pyelitis, pneumonia or influenza could be excluded, operation was justified even though a blood examination failed to show a bacteriemia. An important point in a case under suspicion was taking two hour temperatures in order to accurately note the varying oscillations. In older children there might be headache, pains in the occipital region, and tenderness upon palpation along the jugular vein due to lymph node enlargement. A diagnostic sign of importance was a unilateral enlargement of the lymph nodes at the junction of the facial vein with the internal jugular. The cordlike feel, however, along the anterior border of the sternomastoid was a symptom that the writer had seldom noted even in cases in which the jugular was markedly thrombosed. Other symptoms discussed were nasal hemorrhage, severe persistent headache, and local symptoms. Facial cyanosis and dilatation of the temporal and facial veins, with epistaxis, suggested an involvement of the superior longitudinal sinus. Attention was also called to a symptom which Dr. Oppenheimer said he believed he was the first to describe, namely, dysphagia. Upon examination of the throat there was found a unilateral enlargement of the lymphoid tissue along the posterior fold of the pharynx. In the later stages of the disease, edema about the orbit and a protrusion of the eye on the affected side indicated involvement of the cavernous sinus. These local signs could not be relied upon alone as a means of diagnosis, but their close association with a more definite general symptomatology placed upon them their dependable value. Among the diseases that might give a symptomatology like that of sinus thrombosis and which must be excluded before making a diagnosis of sinus thrombosis were pneumonia, typhoid fever, acute endocarditis, malaria, and certain cases of scarlatinal infection. The accurate diagnosis frequently demanded the closest cooperation of the otologist and the experienced pediatrician. In infantile hemiplegia, sinus thrombosis should be considered. In a series of 78 autopsies reported by Starr and Westcott in infantile hemiplegia, sinus thrombosis was found in five. Blood examinations furnished reliable data in many cases. In the early stages of thrombosis the blood showed as a rule an increase in the number of white cells, but rarely over 20,000. When the thrombosis was infected or suppurating a bacteriemia might be demonstrated by blood culture, but in many cases a clinical diagnosis might be positively made before the blood culture could be obtained. A negative blood culture did not necessarily mean that the sinus was not involved. In an experience dealing with practically 150 cases of sinus thrombosis, the essayist stated that he had never observed an infection due to any organism other than the streptococcus or the *Streptococcus mucosus*. This point had proven in many instances of great value in the expression of an opinion, and showed the importance of a culture from the pus contained in the mastoid process at the time of operation. The prognosis of sinus thrombosis in children depended upon the duration and extent of the disease and upon the stage at which its progress was checked by surgical interference. The earlier the operation the lower the mortality. After metastatic processes had developed in the lungs, brain, joints, or heart, the mortality was

extremely high. The treatment of sinus thrombosis was entirely surgical. The operative procedures were attended by the cure of a great many cases which would otherwise terminate fatally; hence the importance and the urgent necessity for early diagnosis, in which the pediatrician could cooperate to excellent advantage with the otolaryngologist, to whom of necessity fell the operative treatment.

Dr. HERMAN SCHWARZ said Dr. Oppenheimer had given a very clear picture of marasmic sinus thrombosis. He would like to know Dr. Oppenheimer's experience with otitic thrombosis in infants. With the exception of one case that he saw with Dr. Oppenheimer, he had never seen another in such a young child. This was important in diagnosing fluctuating ear temperatures in infants.

Dr. OPPENHEIMER said that the youngest case of sinus thrombosis that had come under his observation was the one to which Dr. Schwarz had referred and which he saw in consultation. Unfortunately that patient had many complications; in addition to the sinus thrombosis the child had a meningitis, diphtheria, and brain abscess. The child died. Last year he saw three children with sinus thrombosis, but up to that time he had never seen a case of sinus thrombosis in a child under five years of age. He had had the opportunity of studying about 150 cases of his own and possibly had seen 50 others in consultation with other men. Of these, there were about twelve cases in children under ten years of age. As to the relative frequency of sinus thrombosis as a complication of mastoid disease, he believed that about four per cent. of all cases of mastoid disease developed some type of intracranial complication, and probably 60 per cent. of these complications were in the nature of a sinus thrombosis.

Some Experiences with Malaria Among Children in Palestine.—Dr. SOPHIE RABINOFF read this paper, by invitation, in which she described her experiences as a member of a medical unit working among the civilian population of Palestine from July, 1918, to July, 1919. She stated that her first work was in a children's hospital of twenty-five beds in Jerusalem, where the service consisted of cases of malaria, dysentery, gastrointestinal conditions, pneumonia, typhoid fever, and influenza. The children's clinic in this city was filled to overflowing. They saw daily from one hundred to two hundred patients. Two months later, when Palestine was opened up by the spectacular advance of General Allenby, detachments of physicians were sent north to take care of the civilian population in the newly opened territories, and she was sent to Jaffa. Here an emergency hospital was opened and later a small children's hospital of twenty beds. Altogether they treated over 2,000 cases of malaria among children. Their clinical routine was as follows: Each patient on the first visit had a complete physical examination, a blood smear was taken, and if the child was under two years of age it was weighed. Notes were made of any abnormality, and the size of the spleen indicated in every case. The classical cases of malaria offered no difficulty in diagnosis, but they soon found that malaria presented every symptom and symptom complex conceivable, and simulated almost every disease known to pediatrics. Furthermore, cases of pneumonia, typhoid fever, and influenza caused a lighting up of latent malarial processes, often obscuring the entire picture. They soon found that there was a typical malarial facies, characterized by pinched, ashy blue or yellow color, blue lips, anxious drawn nostrils, and beads of perspiration on the forehead. In comparing the symptoms of malaria in children with those in adults there were several outstanding features. The chill was much less frequently an initial symptom. On the other hand there was a greater tendency to convulsions and other nervous manifestations such as restlessness, twitchings, fretfulness, or drowsiness. In addition, in children under two years of age there were very frequently gastrointestinal symptoms, such as vomiting, constipation, diarrhea, and occasionally bloody stools. Also the interval between the attacks was marked by a striking return to normal appearance. There was a much greater tendency to irregularity in temperature than in adults. The youngest patient was an infant only a few hours old. The mother had suffered from chronic malaria for several years, with acute exacerbations from time to time. She had received quinine hydrobromide together with morphine sulphate in very small doses since the seventh month of her pregnancy. This seemed to keep the fever in check, though her blood would from time to time show tertian organisms. Dr. Rabinoff cited a number of cases, among them being a case with gastrointestinal symptoms and recurrence, a case with gastrointestinal symptoms simulating an attack of appendicitis, and a case of cerebral malaria in a child of 11 years. She discussed a group of cases with pulmonary symptoms, which offered many difficulties, especially as the influenza epidemic appeared at the height of the malarial season, and one condition complicated the other. Many latent cases lighted up during the period of lowered vitality attendant upon the influenza. Cases of blackwater fever were not uncommon in the lower part of Palestine, though they had but four cases of this malignant form of malaria associated with hemoglobinuria. There was a tradition there among the laity and a good many physicians that quinine taken during the height of the fever would cause this condition. Enlarged spleens were noted in 70 per cent. of the children treated, varying in size from those that were easily palpable below the rib margin to those that extended into the pelvis. In some cases the rapidity with which the spleen increased in size and consistency was remarkable. The chronic cases all had tremendous spleens and were hard to treat. In the treatment of their cases quinine was given by mouth in all their simple cases. Where it was tolerated at all it could be given in fairly large doses. In a certain group of cases it upset the stomach when given in simple solution, but when made up with a simple syrup or with licorice, it was better tolerated. They had none of the more elegant preparations used here. A small percentage did not tolerate the quinine at all when given by the mouth, and in these it was given in suppositories or hypodermically. In all cases in which the attack was ushered in by convulsions, or the symptoms were very severe, and in all cases of malignant tertian or estivoautumnal malaria, the quinine was given hypodermically in doses of one-half grain. All the quinine preparations were very irritating when given in this way, although the hydrochloride and dihydrochloride were the best, but must be carefully given. In the majority of cases there was no difficulty in controlling the acute attack, when the quinine was taken regularly and attention was given to other measures such as rest, proper hygiene, and simple nourishing food. The writer felt certain that relapses would not occur so frequently if the proper treatment was instituted at the start and persisted in for a sufficiently long period. Often cases treated at home did not respond, but on admission to the hospital would clear up promptly. It was very difficult to make the patients continue the quinine after they were over the acute attack, and the result was that they continued to harbor the organisms somewhere until such time as their vitality was lowered and then a lighting up occurred. These quiescent cases acted as carriers of the disease. The chronic cases were very resistant to treatment, but some cases in which quinine by the mouth did not help at all and in which a course of six or seven doses was given intramuscularly, and then followed by quinine and arsenic given in the ordinary way, showed marked and rapid progress. In ten cases, Dr. Rabinoff said, she had used neosalvarsan intramuscularly, with apparent immediate benefit, but relapses occurred when they were not followed by quinine. Change of climate was found to be a very good adjuvant to quinine.

Dr. GAYLORD W. GRAVES asked what the effect of quinine was when given at different stages of the attack. He said it took several hours for quinine to saturate the blood plasma and it was customary for physicians to treat malaria by giving quinine every few hours. Dr. Tuttle at the Presbyterian Hospital had suggested that in the case of a patient who had passed through a chill one should wait until the next chill and at its height give ten grains of quinine. They did this in a case and the patient had no subsequent chill. The quinine was repeated but at such an interval that it was evident that the initial ten grains did the work. Dr. Graves related the history of another case of malaria in which it was evident that the large dose of quinine although given late had mitigated the severity of the chill one-half. The day following admission he had another chill, making it seem likely that there were two

broods of parasites. Quinine given at the height of this chill controlled the infection so that there was no chill two days thereafter. After several months this patient was seen outside the hospital for an illness diagnosed as influenza. Several days later the spleen was found enlarged and the temperature 104° F. At this point quinine was given and no further chill occurred, although blood examination revealed the malarial parasites. Dr. Tuttle, though giving no explanation of this, had suggested the theory that continuous administration of quinine discouraged the emigration of parasites from the corpuscles while if one waited until they were really out and then "hit them on the head," as the speaker interpreted the theory, the effect was more pronounced. He would like to know whether the psychological moment to administer quinine was at the height of the chill or before as was customary.

Dr. SCHWARZ asked Dr. Rabinoff what the mortality was in the cases she had seen. It was interesting that in Italy a great proportion of infant mortality was made up of deaths due to malaria.

Dr. HUGH CHAPLIN stated that in chronic cases of malaria they had noticed a slight, rather constant, rise in the evening temperature to 100 to 100.5 degrees, rarely over that. They had one case of malaria in a child, in the Orient, treated for about a month with quinine, and after that for a number of months the child had a slight rise in temperature in the evening. There might be other explanations of this rise in temperature, as possibly a slight indigestion, or a tuberculous family history, but neither seemed to account for the rise in temperature in this case. They did not find the organisms until later when the child had a chill and then the organisms were present. Was the chill in this case due to organisms that had been lying dormant during this period?

Dr. CHARLES HENDEE SMITH emphasized the importance of giving quinine in small doses for at least six months after the acute attack in order to prevent recurrence. He did not think that point had been sufficiently emphasized in the paper. Another point was that rest in bed prevented the recurrence of paroxysms as well as though quinine had been given. Then if one allowed the patient up he got another chill and one would find the parasites. The point he wished to bring out was that one got a great deal more good out of the quinine if the patient was in bed. For that reason it was advisable to put the patient to bed for a week on half doses of quinine and when he got up to keep on giving small doses of quinine for many months.

Dr. H. L. DOWD stated that bicarbonate of sodium and lemon juice had proved efficacious in malaria. It was said that the lemon juice, because of its citric acid, acted on the blood cells favoring absorption of the bicarbonate of sodium. They had used cacodylate of sodium as a preparation associated with hydrobromide, giving both hypodermically.

Dr. MURRAY H. BASS referred to a paper which he read some six or seven years ago in which he reported the case of an infant in whom the malarial parasites were found a short time after birth, and he had decided that in this instance the disease was of congenital origin. He would like to know what Dr. Rabinoff's experience was with reference to malaria in such young infants.

Dr. RABINOFF, in closing, stated that in a series of experiments in the literature it was shown that quinine by the mouth was mostly excreted in from three to six hours, and in giving large initial doses at the time of the paroxysm, one controlled the organisms in the blood but this had no effect on the spores developing later, and for that reason it was necessary to continue giving the quinine at short intervals. Her experience had shown that quinine must be continued for a long time after the acute attack was controlled. The spores were supposed to develop in five or six days and were responsible for subsequent relapses. In regard to the question of the mortality from malaria among infants, she herself had not seen any deaths due to the malaria itself, except in one case with convulsions, in which death occurred during the attack, and in this instance the pathologist thought there was a direct obstruction of the cerebral vessels which was responsible for respiratory failure. There were children among their chronic patients who ran a daily temperature of 100 to 101° F., and who gave a history of having had this temperature for weeks. Rest in bed was very important. Many cases treated at home without success, when admitted to the hospital and put to bed responded by a drop in the temperature within a day and there would be no further rise in the temperature while they were in the hospital. In regard to Dr. Bass's case of malaria in a young infant, Dr. Clarke of Johns Hopkins had examined the fetal maternal blood in cases of malaria in young infants and found that in these cases there had been some trauma in the placenta which permitted the organism to pass from the maternal to the fetal blood.

Health Classes for Children.—Dr. IRA S. WILE read this paper in which he said that localized health agencies for children of school age, including medical inspection of schools, school nurses, drafting of adequate educational laws, the formation of little mothers' leagues, were in a way types of health classes. To these might be added an increased stress upon the hygiene of teaching and the teaching of hygiene in public schools, although it was doubtful if these functions were performed as satisfactorily as might be desired. The general purpose of health classes was the accentuation of correct rules for living and also for the discovery of defects and handicaps. Health classes taught unity of body, mind, and soul, and placed in proper perspective their relation to the welfare not merely of the individual child but of the entire family taken as a unit, and in this way one was enabled to approach all problems relating to the child from a single center. This required an understanding of medical psychology, and of social and economic problems, which were so thoroughly interwoven with the development of healthy and healthful family life. There was such a thing as a healthy character and its formation should not be neglected in the ordinary method of conducting health classes. The single unit health class was preferable and segregation should not be permitted to develop. If a child in the health class required the care of a dentist, he was sent to the dentist and then returned to his class; in the same way, if a child was undernourished or had some other trouble that needed special attention, he should have such attention, but he should return to the general health class. At Mount Sinai health classes were being conducted, working through the family as a unit. They worked for health education without instilling fear of any of the diseases that might attack childhood. Work was not done through the stimulation of fear, for fear was practically an anxiety state and woefully bad psychologically and also a pretty low motive from which to act. The purpose of such classes was to elevate the family standards of living, to eliminate the two great curses, ignorance and poverty. In the matter of administration provision was made for thorough physical examination, the keeping of complete records, and follow-up work. In the keeping of records and the follow-up work the services of a nurse and a social worker were used, and there was also work for a certain number of volunteer aids. There was also a field for a domestic science expert and a psychologist. The physician made the examination but did not, as a rule, prescribe. Directions to the patient or to the nurse must be given in detail. For instance, one should not give the general direction, "to take exercise," but definite instructions as to the kind of exercise. They used cards of three colors, blue, yellow, and white. They patient on admission received a blue card and as he progressed was advanced to classes designated by blue and white cards. It had been found that such a system aroused competition and added greatly to the effectiveness of the work. The discipline in the classes was not formal. The room where the patients waited was very different from the ordinary morbid dispensary room. The walls were hung with charts, teaching food values, the proper kind of wearing apparel, methods of making a fireless cooker, or an icebox at home, etc. The patients were not compelled to be silent but were encouraged to talk, especially on health matters. Everything in the environment and attitude of the personnel was directed to creating a joyous and healthful atmosphere. In summarizing, Dr. Wile characterized health classes as an expression of humanized medicine, seeking through

medical psychology, educational, social, and economic means to build up generations of children who should be a credit to themselves, their families, and their nation. They should be powerful, but self-controlled; metally alert and without indolence; spirited but spiritual; capable of living in the fullest measure a life that should be rich to enrich their communities in all that accrued from health, which was wealth and happiness.

Dr. CHARLES HENDEE SMITH said there were so many different aspects of this subject that might be discussed that it was difficult to know what to start upon. One of the most interesting points was that one could get results at once in almost any child that came into the class. The child would gain in weight for several weeks and then as some one had said "Grow weary in well doing" and slump. A continuous gain depended entirely upon the boosting ability of the man in charge of the class. It was necessary to reach people from many different sides, social, economic, etc. This kind of a class reached the cause of ill health and malnutrition by educating mothers to take proper care of their children in the home. Caring for a child in the home gave much better permanent results than sending the child away from home for a short time, as when this was done the child very frequently fell back when he returned to his home. It was all right to send a child away to get a start, but that did not correct the cause of the trouble. One reached the cause of the trouble by educating the mother and improving conditions in the home. There could not be too many of these classes. There should be one in every hospital and in every school. Until they could get the public school teachers to attack this problem they could not expect to have the kind of people the country should have. Until the nation realized that the foundation of good health lay in education they would go on having hospitals and dispensaries which had to do what they could of this kind of work.

Dr. JACOB SOBEL said that the most significant thing in connection with this paper was that Dr. Wile had started something, and by that he meant that Dr. Wile was a pioneer in starting classes for children of the pre-school age in connection with hospitals. To show how little effect one pre-school age class had on this very large problem one had only to consider that there were approximately 475,000 children of pre-school age in New York City. It would require a large number of clinics and a large personnel to care for the children of this class. This was probably the most pressing question before the country to-day. The proper care of the pre-school child bore the same relation to the school child as the problem of prenatal care bore to the infant. How to care for these 475,000 children in New York was a serious problem. It was not a municipal problem alone because the municipality could scarcely handle it. There were from 275,000 to 300,000 children of school age physically examined annually in New York City and this required a large number of doctors and nurses. This being the case one could readily appreciate what a working force would be required to examine 475,000 children of pre-school age. The only solution of the problem was along the lines which Dr. Wile was working and in accordance with Dr. Smith's suggestion. In order to make any impression it was not only necessary to have municipal clinics and pre-school clinics, but these health classes must be associated with every hospital, dispensary, settlement, day-nursery, and school. Dr. Sobel said he did not know just what Dr. Wile meant by caring for the mental condition, but this should include the emotional as well as the mental make-up. It was true as Cardinal Newman had said, "If you give me a boy until he is seven years of age I care not who has him afterwards." The care of the child at this period of his life should not be overlooked. He hoped the time would come when the municipality would spend more money in this direction, for if they spent a large amount of money on the pre-school child they would not require so much for school medical inspection. The pre-school examinations should be carried on at community centers, and the child prepared for school entrance and to assimilate knowledge; this would mean a saving for the children, a saving of expense to the municipality, and a saving to the state and the nation.

Dr. WILE agreed with Dr. Sobel that public money could not be spent to better advantage than in giving proper attention to children of pre-school age. He also urged that private practitioners be more careful in looking for physical defects in children, and that this be also borne in mind by doctors treating children in public clinics. He felt that if they would all get together it would be possible to make a slight dent on the whole problem.

Butter Fat and the Child's Weight.—J. H. LARSON, secretary of the New York Milk Committee, made this presentation by invitation. He showed graphically the weights of ten children selected from a group of resident children at an orphans' cottage home at Rochester, N. Y., the records having been obtained during a recent survey of the Rochester milk supply under the direction of Dr. Charles E. North. The weights shown were recorded at six-month intervals during two years and a half previous to the end of 1918. Though the cottages had a population of about thirty children so few were taken because the population was constantly shifting through discharges and admissions and also because weight records were not taken from the histories of any children who were under medical treatment or for whom had been prescribed medicines or emulsions of any kind. In other words, the data was limited to those children who were sufficiently normal as to health and general physical condition to be considered as not needing medical supervision. From the table it was observed that there was a gain in weight for each six months with the exception of the fourth six-month period, namely, the period between January 1 and June 30, 1918. The explanation offered for this by the superintendent was that because of his desire and that of the governing board to comply with the request of the Federal Government for food conservation, particularly animal fats, that during the first six months of 1918 oleomargarine was substituted for butter in the diet of the children and the workers in this home. The table showed that nine of the twelve children lost weight during this period. One girl who was considerably above the theoretical weight and height of a girl of her age did not lose weight during that period, though her progress was slightly retarded as compared with her gain during the previous and succeeding butter periods. The superintendent of the home was authority for the statement that the oleomargarine contained no butter, and this statement was corroborated by the manufacturer of the product. The gain in weight during the last six months when butter constituted a part of the diet showed that the children not only experienced a normal gain, but that they made up the loss in weight they had suffered during the previous six months, or the oleomargarine period. In other words, they had a progressive increase in weight during the two and one-half years, upon which the influence of the oleomargarine period was insignificant.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

SHELL-SHOCK AND OTHER NEUROPSYCHIATRIC PROBLEMS. By E. E. SOUTHARD, M.D., Sc.D. 982 pages with illustrations. Published by W. M. Leonard, Boston.

THE PRINCIPLES OF GYNÆCOLOGY. By W. BLAIR BELL. 660 pages with illustrations. Published by William Wood & Co., New York.

GRUNDRISS DER PHYSIOLOGIE ZWEITIR TEIL: BIOPHYSIK. By Prof. Dr. O. WEISS. 454 pages with 170 illustrations. Published by Georg. Thieme, Leipzig.

PRAKTISCHE BAKTERIOLOGIE. By Dr. L. PANETH. 158 pages with 7 illustrations. Published by Urban & Schwarzenberg, Berlin and Vienna.

THE NUTRITION OF THE FETUS. By J. MORRIS SLEMONS. 49 pages. Published by Yale University Press, New Haven.

YEAR-BOOK OF PHARMACY. Editor of the Abstracts, J. O. BRAITHWAITE. 548 pages, with illustrations. Published by J. & A. Churchill, London, England.

APPLIED CALCIUM THERAPY:

A STUDY OF DEFICIENCY DISEASES.

BY JOHN AULDE, M.D.,

PHILADELPHIA, PA.

IN a study of the medicinal properties of calcium, or lime salts, it will be worth while to review briefly the function of minerals from both the physiological and chemical viewpoints—because the mineral constituents of the human body determine or decide the capacity and stability of the various structures, bone, muscle and nerve. Included also in this category we have the digestive apparatus, the urinary system, the glandular appendages and the reproductive organs. Although my studies extend over a period of more than twenty years, during which time I have published numerous papers, the subject of calcium therapy has received but slight attention—until within the past few years. In my early studies I found a considerable literature devoted to the scientific evaluation of calcium salts, but I had to work out the clinical applications without the aid of laboratory tests as a means of control. More recently, laboratory investigations relating to the dietary of humans, experimental studies to determine the effect of dietary restrictions upon animals, together with the gradually increasing number of favorable clinical reports bearing upon the empirical employment of the calcium salts, encourages me to make an effort to elevate this practice to the position it is entitled to occupy, that is, the scientific and practical.

The proposed study will naturally include an inquiry into the essential factors responsible for various diseased conditions which we know are traceable to dietary deficiency—although it would be impossible to cover the entire field even in a lengthy article. In addition to this, the item of infection should not be overlooked. Thus, it will be evident that we have to deal with a multiplicity of delicate and complex relationships involving both physiology and chemistry—as well as the personal equation, the psychological factor, not to mention the biological questions. Such a substantial foundation is demanded as a preliminary to the clinical demonstration that calcium deficiency in the blood and tissues is a common condition and a serious obstacle to recovery in all disease, acute, subacute, and chronic, infectious and noninfectious.

In order to maintain the reader's interest, and if possible secure his active cooperation in the laudable work, let me refer to a recent clinical report which shows how very near investigations may approach the actual solution of a mysterious or occult problem, but fail simply because they fail in persistence.

Thus, Howland and Marriott reported eighteen cases of idiopathic tetany (convulsions) occurring in children in which the calcium content of the blood serum showed a deficiency of approximately 40 per cent., and the administration of calcium chloride with the food proved efficacious. Their conception of the malady is, "that some factor, at present unknown, causes a reduction of the calcium content of the blood," and an editorial writer (*Journal, A. M. A.*, Feby. 15, 1919, p. 496), remarks that it is "this profound phenomenon that remains to be discovered" because "scientific curiosity . . . seeks the ultimate causes of disease."

Apparently, *this "profound phenomenon" had been completed explained* in the report of Dr. Rogers (*Lancet*, December 1916), a British medical officer, India service, in the form of a clinical record of 1,000 cases of uremic poisoning in the algid stage of cholera. Upon adding 4 grains of calicium chloride to the pint of physiological salt solution for transfusion the mortality was reduced 70 per cent.

For the benefit of the general practitioner who has not read up on experimental investigations and would be inclined to doubt the value of such a small dose of the calcium, it will be in order to analyze the situation, as follows: There are two types of uremic poisoning—one with profound depression, in which the output of ammonia is largely increased, but there are no convulsions; in the other the excretion of ammonia is retarded, convulsions being the dominant feature. In all cases, however, the calcium content of the blood is deficient, so we have a condition analogous to that found in convulsions in children, but the pathology still remains obscure.

It may be of some practical assistance in this connection to mention that Noël Paton some time ago advanced the suggestion that convulsions in children were brought about by or through "an error in the chemical exchanges of the organism," and he placed the responsibility on guanidine derivatives, but the writer is of the opinion that we can reach a more substantial basis, one that is susceptible of actual demonstration. For example, certain animals, deprived of the suprarenal cortex will die from convulsions similar to, if not identical with those occurring in uremia, and yet the blood urea in these cases is below normal, and besides, urea is not poisonous. As a matter of

fact, uremic poisoning is a myth, because it can be shown that calcium depletion interferes with glandular activity, and this is "the error in the chemical exchanges of the organism," and the evidence will be complete when we have demonstrated how calcium depletion is induced.

Laboratory investigations come to our aid here by demonstrating that an enzyme produced by the thyroid gland is responsible for converting ammonia from the systemic nitrogen, that another enzyme from the suprarenal cortex acts upon ammonia, changing it into a poisonous substance, and finally, a parathyroid ferment converts this toxic principle into the harmless urea. That is to say, the poison of uremia is an intermediate product between ammonia and urea and results from glandular deficiency. Will it be considered a gratuitous assumption that this explains in a measure "the error in the chemical exchanges of the organism?"

Of course, the evidence is not complete, but it will answer as a working hypothesis. Any tissue, muscular, glandular, or nervous, may cease to function owing to bacterial infection, traumatism, or chemical deviation, and it is the latter we are required to deal with in the cases under consideration. In all cases of illness, acute and chronic, infectious and noninfectious, there is an initial period of increased alkalinity—nature draws ammonia from the blood and tissues, and at times this is successful, as in the profuse sweating, free bowel movements, increased flow of urine, etc., but this effort has its limitations. Then follows an acid excess, the alkali reserve is reduced and the oxygen-carrying capacity of the blood is lessened, and this is substantially the condition we have to contend with in the case of convulsions in children—idiopathic tetany—and in the so-called uremic convulsions. There is defective glandular action due to calcium depletion, a condition which will be understood from a brief study of the physiology and chemistry involved.

Acid excess involves tissue change, and this deviation modifies function, the diminished mineral constituents in the blood being merely a symptom. The immediate effect is to deplete the calcium content, magnesium taking its place, but while calcium and magnesium are interchangeable and complementary in their action, they are also antagonistic. Calcium being the stronger base, combines with the acid, magnesium taking its place; normal nucleoproteins are converted into magnesium nucleoproteins, which lack the property of imbibition (absorption).* Function may be restored by the administration of calcium —to promote dissociation according to the law of mass action, and this is what is accomplished when calcium is administered for the relief of infantile tetany and the convulsions occurring in uremia.

*This fundamental fact has a direct bearing on Woodyatt's theory of "water retention" in febrile states. "Thirst fever" in edema is due to magnesium infiltration, an acid condition of the intracellular content giving rise to the colloid-chemical deviation. Glucose solution, *an emulsion colloid*, given intravenously, raises the temperature of a dog readily to 111° F., and even up to 125° F., simply because it interferes with the normal function of the intracellular *suspension colloids* of the protein molecule—this effect is entirely independent of any suppositious heat center.

To illustrate: I have a spring on my country place, the water of which carries, all told, 2.7 grains of mineral constituents per gallon, 60 per cent. of which is calcium. The remaining portion, 40 per cent., includes magnesium carbonate, 12 per cent., with sodium chloride 28 per cent., and yet this very small percentage of mineral content, owing to its proportions, enacts the rôle of an active and efficient diuretic, increasing both the urinary water and the solids.

Some ten or twelve years ago I had a chat with Dr. Meltzer regarding the remote effects of magnesium sulphate introduced into the spinal canal for the relief of tetanus. I asked him if it would be the proper procedure, in case evidences of collapse appeared, to administer calcium salts, to which he promptly replied that it would cause instant heart-block, so that accounts for the physiological antagonism.

Perhaps additional evidence will prove acceptable, and shed further light upon this rather difficult problem. During the past year I have administered thousands of intravenous injections of calcium salts, alone, and in various combinations to several hundred patients, and while my investigations are still under way, I may anticipate the final outcome by a very brief reference to some of the interesting and instructive results. In the early stage of typical cases of influenza the intravenous administration of 2 grains of calcium chloride in 10 c.c. of sterile water almost invariably produces profound shock. If the patient is placed in the recumbent posture recovery takes place in a few moments, and within five or ten minutes there are absolutely no subjective symptoms of the disease—and this freedom from the malady may continue for several hours. Other patients, suffering from subacute and chronic disorders showed the same sensitiveness, and to counteract shock in all cases of acid excess, indicated by the salivary and cutaneous reactions to litmus, and the reflexes, a small dose of strychnine arsenite (gr. 1/50), was administered a few minutes before the operation, the results being entirely satisfactory. Later, this flimsy expedient was discarded, substituting in its stead the conjoint employment of calcium and magnesium chloride in exactly the reverse proportions (9 parts to 1), which has been found to produce the optimum growth in plant life, and as a result there were no further untoward symptoms.

An interesting case of persistent insomnia will serve to illustrate the practical side of this question. The patient is a young man, aged 25, employed as a machinist, and aside from a rather sallow complexion gives no indication of disease, but he has been unable to sleep for several months. His appetite is capricious, the bowels are constipated, and he feels tired all the time, more so in the morning than at any other time in the day. The injection produced profound shock, but the patient recovered in the course of a few minutes and said he felt "first-rate." Internal medication included small doses of calcium phosphate, together with gr. 1/200 copper arsenite before meals, and at the end of the week, on a regulated dietary, he reported that he had slept well every night, his appetite was good and the bowels

regular, but the second injection produced precisely the same effect as the first.

This evidence confirms the theory of substitution or infiltration and dissociation, and at the same time accounts for heart-block, as stated by Dr. Meltzer, but the modus operandi of calcium efficiency is not yet exhausted, because it presents a singularly instructive scientific aspect. Both calcium and magnesium are proximate principles and possess several important properties in common—they are antacid, catalytic, and reconstructive. Whatever may be the chemical status in the course of distribution, we know that ultimately they become colloidal and that this is their intracellular condition. As colloids they acquire increased surface energy and enact the rôle of ferments—mineral ferments, but here the analogy ceases. Approximately, calcium constitutes 50 per cent. of the inorganic matter of bone; as compared with magnesium it is in the proportion of 1 part to 3 in muscular tissue and 1 part to 10 in the central nervous system, and this is probably true of the nerve structures throughout the body.

Now, suppose the calcium content of the blood stream is diminished 40 per cent., it follows that the tissues, including nerve tissue, are being drawn upon and unable to meet the demand. When the central nervous system or any part of its mechanism, the muscles, the bone structure, or the glandular appendages, including the ductless glands, are robbed of their essential chemical constituent, their normal function is arrested or destroyed, and this serves further to elucidate the pathology of infantile tetany and uremic convulsions.

Calcium depletion of the tissues, as stated, is brought about by chemical deviation, incident to disordered function, which gives rise to acid excess, and this harks back to dietary deficiency and coincident or consecutive impairment of the digestive capacity. There is substitution or infiltration, and as a consequence, or as a result, the uninterrupted transmission of nerve impulses is hindered, arrested, or destroyed. We have conclusive evidence of this in the successful employment of magnesium sulphate intraspinally for the relief of tetanus and in surgical operations, also in the relief afforded by calcined magnesia (magnesium oxide) in acute bowel troubles in both children and adults.

Perhaps, in the near future, modern laboratory technique will enable the physiological chemist to confirm my belief that oxidase is a factor in this transformation, that it combines with the colloid magnesium particles, forming magnesium oxide, the only known chemical which unites with organic colloids in alkaline solution, and that is my conception of "the error in the chemical exchanges of the organism" that is responsible, not alone for convulsions, but also for a long list of chronic ailments which have resisted the earnest solicitations of our most eminent physicians.

Dietary Deficiency.—To the layman dietary deficiency simply means a lack of food, but to the intelligent physician it has a far-reaching significance. For example, when the physicians connected with an orphan asylum in New York found scurvy making serious inroads on their patients with orange juice unobtainable they resorted to canned tomatoes, when it was demonstrated that the tomato juice answered every purpose—but these children would not have been susceptible to scurvy had their dietary been properly proportioned. At the present time there are probably a hundred thousand persons in the Southern States suffering from pellagra, a disease which has been a scourge in Southern Europe for more than a century, but competent investigators appointed by this government have shown that the disease does not penetrate the mountainous sections of the country, where the grain supply for the family is provided by the local facilities. In this instance, at least, disease can be traced directly to the use of refined and denatured food. Beriberi, a form of multiple neuritis which has been known to affect entire sections at a time, has been banished by providing what is known as a balanced dietary —and my personal observation shows that the dietary is the most important factor in the treatment of neuritis as seen in this climate. In the case of rickets, no one will hesitate to say the disease has been brought about by or through dietary deficiency, and as the all prevalent disease, tuberculosis, has shown a markedly favorable response to calcium medication, we cannot resist the analogy that here, also, dietary deficiency must be an important factor, producing a condition which makes the system especially susceptible to the infection.

It is not sufficient, then, that a person has all the food he wants—because we know that many such persons suffer from hunger. In other words, the body tissues lack something, and it is this sense that gives them a constant craving for something they know not what. The hunger sense has frequently been so pronounced in hospital patients that the medical attendants seriously considered sending them to an asylum, all because of the mistaken notion that starvation will cure disease—when the disordered mentality may be traced directly to dietary deficiency. This is well illustrated in the record presented by Dr. Graves (*British Medical Journal*, April 5, 1919, "Response of Calcium Shown in Maniacal States"). He found that the action became evident within twenty-four hours following its exhibition. "The acute mental symptoms were alleviated without the production of the stupor so commonly observed after sedative drugs, and the circulatory response was equally interesting. Instead of the rapid, at times almost uncountable pulse with its flaccid artery and low, variable systolic pressure, the pulse became slower, the artery normally constricted and the pulse-wave stronger, indicative of an improved action of the ventricular myocardium."

The foregoing record brings to mind a case submitted to me more than ten years ago for hypothetical treatment. The patient, a woman 39 years of age, living in very ordinary circumstances, had suffered three or four weeks from acute mania, requiring the constant attendance of a nurse, nourishment being administered by means of a tube passed through the nose. Two consultations by a reputable alienist had brought no results and the physician had reached the limit

of his armamentarium. Calcium carbonate, in substantial doses, was recommended, the powder to be added to the milk given through the tube, with the result that the patient was convalescent in two days and made an uneventful recovery, but the doctor had a large bump of skepticism and told me afterwards that he did not report recovery, being under the impression that relief was merely a fortunate coincidence.

Now, it must be perfectly clear to the most superficial observer that unsuitable food, no matter how it is prepared or eaten, will eventually disturb the digestive apparatus, say the stomach or the intestinal tract. Thus, we have decomposition of animal foods in the stomach and fermentation of the starchy foods in the intestine; and if the stomach is dilatory, or unable to perform its functions in digesting all the animal foods introduced, this partially digested and decomposing food is carried along to the lower bowel where microbian digestion takes place—it is under such conditions that patients complain of the fetid breath. In these circumstances, the liver is called upon to perform extra work in destroying or oxidizing the poisons thus formed, but after a while this organ also complains, and unless it receives better treatment, it rebels, in the form of inflammation or abscess. The pancreas is likewise intimately connected with these disturbances, the nervous mechanism of which is rather complicated, but there is no obscurity when diabetes supervenes.

Similarly we can trace the incipiency of such disorders as kidney affections, showing their relation to blood dyscrasias, and the same is true of disorders of the nervous system, because the fact is patent that derangements of this character are not of mushroom growth, they do not spring up over night.

Reference should be made here to disorders of the lymphatic system and their special relation to deficiencies in the ductless glands, for it must be apparent that the functions of both are closely related and interdependent. Take almost any class of dyscrasias, such as derangement of the central nervous system, heart affections, and even intestinal disorders, it must be apparent that physiological or chemical deviations in the blood-vascular system must produce a corresponding deviation in the lymph-vascular system. Thus, when the blood is deficient in calcium and is surcharged with acid the normal function of the lymphatic glands is hindered or destroyed, and in proof of this we have but to observe the increasing number of fatalities from what is clearly and demonstrably due to embolic infection. Indeed, it is not too much to claim that a sluggish lymphatic system is largely responsible for many if not most of the so-called chronic ailments, and there can be no question but that so-called catarrh stands at the head.

For the correction of dietary deficiency as a means of avoiding the pitfalls and disasters incident to chronic ailments, it is necessary that we should impress upon our patrons the importance of the dietary and use our best endeavors to advise them of the most practical methods of selecting the essentials. Thus, it is the first essential that the protein selected should be of good quality in order that the rebuilding process may be regularly and persistently maintained. This is a most important factor during childhood and adolescence, but it is none the less essential during the entire period of adult life, if it is desired to maintain health and promote longevity. What, then, is the outlook, if we are to judge the public by the "system" outlined in the following colloquy between two women in a department store—an actual occurrence: "We've just simply decided to do without meat altogether. I said to John—" "Oh, we have too, and instead of butter we're using—" "Of course we have to have milk for the children, but cream—" "Did you say you'd take the blue broadcloth, too, madam—" "Yes, all three. And John hates to give up his bacon and eggs, but—" "Harry never takes anything but a little toast and—" "Yes, madam, the three come to $245." "Very well; charge. Yes, dear, dear, everything so high."

When starchy foodstuffs are taken in abundance, with or without fats, the tendency is to create corpulency, but this is rather a disadvantage than a benefit, and in time it is bound to react, because the normal facilities for manipulatings fats, sugars, and starch are overtaxed and the artificial structure falls to the ground like a house of cards—along comes influenza, typhoid fever, erysipelas, a succession of boils or a carbuncle, or even a slight (?) ailment like tonsillitis, and it is like throwing a monkey wrench into the machinery.

Disease an Effect.—It is not necessary to discuss the negative side of this self-evident proposition, but an investigation of the various causes which contribute to produce the effect will prove interesting and instructive. Time was when it sufficed to state that the causes of disease were either extrinsic, like diphtheria, typhoid, scarlet fever and tuberculosis, or intrinsic, such as coccus infection, involving the teeth, the sinuses, the pleural cavity, the bronchial tubes, or the bladder. Even most cases of indigestion were regarded as endogenous. Now, we are compelled to correlate physiology, psychology, and chemistry as essential factors in the cause of disease, and this conclusion by no means excludes infection. However, it will be developed that infection, so intimately connected with, and dependent upon, chemical deviation, must be regarded as a physiochemical problem and treated as such.

For example, a person feels slightly indisposed; the following day he seems more depressed and decides to consult the doctor, who makes an examination and advises him that he is suffering from some minor ailment, which at the time is in its incipiency, tonsillitis, gastritis, intestinal indigestion, or influenza. Whatever the ailment, there is a physiological change, and coincidentally or consecutively sensation is affected. In addition, we must consider the probable chemical changes—in the blood and in the tissues, including nerve tissue—and, of course, the entire morbid complexus hinges upon impairment in nutrition, or lessened resistance, by or through the inorganic depletion incident to the chemical deviation. And the function of the ductless glands must not be overlooked in studying the pathology.

To illustrate in a general way the practical value of calcium medication the following records are presented:

Miss S., aged 19 and the picture of health, has been compelled to give up her course of study to become a nurse. There is pronounced spondylitis, the entire spine is exquisitely tender; there is a well-marked pyelitis and anuria has reached the danger point, not over six ounces of urine being voided in the twenty-four hours. The most forbidding symptom, however, is an inflamed left ovary; at the menstrual period the external tumor is half the size of an orange, and is attended with excruciating pain, the menses being irregular and scanty, with profuse leucorrhea.

Medication included substantial doses of calcium sulphide and calcium phosphate together with eight to ten glasses daily of the spring water mentioned along with a regulated dietary—with the result that the urine was promptly increased in quantity, the pus disappeared, pain along the spine became less acute, and the ovarian pain gradually subsided, so that the third menstrual molimen appeared without warning and was apparently normal in every respect.

Mrs. P., aged 39, of medium height, but very thin—weight has been reduced from 140 pounds to about 90—has been under treatment for abdominal pain for over a year, first with the local physician, then with specialists. She was for six weeks in a sanatorium, where treatment was conducted for tuberculosis, because there was continued elevation of the evening temperature—100° to 102.5° F. Last November she consulted a well-known local surgeon, who pronounced her malady cancer, adding that she would not live beyond the following February, and it would be far better that she died sooner, because of the continued pain incident to the progress of the disease.

The psychological factor in this case was predominant. The lady's husband called upon me the latter part of May, gave me a complete history, and from his description I was of opinion that it was a clear case of mebranous enteritis. There was almost constant pain and tenderness in the right hypogastric region with recurrent attacks of severe pain, and following these attacks the stools were charged with shreds, and this experience had been almost constant from the earliest history of the case. The gentleman said his wife had given up all hopes of recovery and had positively refused to see another physician; she was persistent in her belief that if eight doctors had utterly failed to relieve her sufferings it was useless to make any further effort. However, I offered to take a chance in order to effect a reconciliation, and as a result of the employment of calcium sulphide conjointly with copper arsenite she began to improve, but she was not able to stand the journey to the office.

On June 15 this patient came to the office, when the diagnosis of membranous enteritis was confirmed, about ten inches of the transverse colon, including a portion of the hepatic flexure, being involved. The temperature was 100° F., the pulse 120, and the patient appeared to be so frail that she was advised to remain in bed, or lie on the sofa during the day, returning when she had gained sufficient strength. On August 7, the patient returned, much improved, reporting that the temperature was normal most of the time, that no more shreds had shown in the stools, and that she had a good appetite, and was conforming as far as possible with the dietary instructions; but the pulse was still rapid, 108 per minute, and there was considerable tenderness over the affected area on percussion. At this visit she had an intravenous injection of colloid copper arsenite, 3 c.c. in 10 c.c. of sterile water, and apparently this proved the turning point in the treatment, as she returned a week later greatly improved. At this visit she had a second intravenous injection, and from that time forward recovery had been persistent and uneventful—weight, October 1, 107 pounds. The menses, arrested for six months past, have reappeared, normal in every respect.

It remains to be added that the disorder was clearly an effect, the cause being traceable to unsuitable dietary, giving rise to intestinal indigestion, acid excess with calcium depletion, and along with this we had a disordered liver function which, of course, received careful attention, but coccus infection cannot be excluded.

Too much stress is liable to be laid to the infection while the physical condition of the patient is neglected, as the following case will show. It should be passed as a concrete illustration of deficiency disease.

Mrs. M., aged 26, and six months pregnant, presents every symptom of physical exhaustion. Her oldest child is three years of age and another is nine months, and for the past five months she has suffered continually from nausea and vomiting. Besides, she has tuberculous infection and her physician has told her husband that it would not be for the safety of the unborn child to take treatment, so that no medication has been advised for either condition.

Physical examination discloses infiltration involving the left apex anteriorly, with moist râles, together with prolonged expiratory murmur posteriorly involving the right apex; the temperature is 98° F., the pulse-rate 84, and aside from some puffiness of the feet and ankles there are no untoward symptoms.

Treatment was begun on Friday, one and one-quarter grains of calcium sulphide together with 10 grains of calcium carbonate to be taken before meals, and along with this a regulated diet. The patient reported on Monday that the nausea and vomiting had subsided, that she had a good appetite and had eaten freely; also, that the cough had almost disappeared, being noticeable only in the morning and on lying down at night and that the expectoration was much diminished. She also brought a specimen of the sputum which the chemist examined and sent the following report: "Soft mucus, moderate amount of pus; no blood and no streptococci; tubercle bacilli are not numerous."

On receipt of this report, hypodermic injections of nuclein charged with a small percentage of formalin, every other day, were added to the treatment, with the result that improvement was perceptible from day to day—the apex infiltration area improved, the prolonged expiratory murmur disappeared, the swelling left the feet and ankles, the patient slept well, the appetite improved, and to all appearances she was in perfect health. A second sputum examination two weeks later showed, "Not many tubercle bacilli," and I feel confident that the infection will be cleared up completely in the course of a few weeks.

There is a densely populated and rapidly expanding twilight zone situated midway between heart disease and neurasthenia which supplies us with a vast number of variations illustrating deficiency disease. The men included in this catagory drop off suddenly, at the dining table, on the street, or in their office chair, but the women, for the most part, are carted off to the sanatoriums, where they are treated with dialectics and subjected to foolhardy dietary restrictions, all of which are of slight practical benefit, simply because they do not aim to correct or relieve the paramount defect, the mineral deficiency which has developed gradually as a result of the long continued acid excess. The following characteristic cases are offered in evidence:

Mr. B., aged 46, is apparently well nourished and "looks" it, although his weight has been reduced from 170 to 156 pounds, but for the past two or three years he has suffered from "nervousness," and since his business requires that he employ considerable help, the uncertainty in prices has not contributed to his comfort. He has consulted several physicians without benefit, and that, together with the conflicting diagnoses, leads him to believe he is a very sick man. One gave him dilatation of the heart, and this along with the occasional attacks of dizziness, has created not a little alarm, because he reads the newspapers.

Physical examination shows slight valvular incoordination, pronounced intestinal indigestion, and, in addition to this, we have an inactive liver. The salivary reaction is normal, the knee-jerk exaggerated, the pulse-rate is 72, but there is increased arterial tension with the second sound of the heart accentuated.

In the treatment of this class of cases it is of first importance to counteract the substitution or infiltration, and in the case under consideration it is possible to do this, when the "nervousness" and cardiac derangement will disappear. The treatment for the emergency is of permanent value, and collateral treatment for the indigestion, the inactive liver, or the sluggish condition of the lymphatics may be instituted at the same time. In the present instance it seems that the liver function received first attention, while my record shows that the emergency treatment included calcium iodide and phosphate, one and a quarter grains of each together, before and midway between meals, that is, five times a day. At the end of a week the "nervousness' was completely under control, the patient said he felt greatly improved and encouraged, but the valvular incoordination was still present, and for the relief of this symptom, collateral treatment was discontinued for the liver and calcium sulphide substituted, under the impression that this would "stimulate" the lymph-glandular system—and it proved a success. It is sufficient to add that this patient made a complete recovery.

Mr. L., aged 49, is an executive official in a large corporation. During the war he says he acted on as many as a thousand telephone calls in one day, but he finds it difficult to get away from himself, introspection seems to have gotten the better of him. He has consulted several physicians and become discouraged. It is practically impossible for him to concentrate his mind for any considerable time upon even the most important business problems which are coming before him for decision from hour to hour. One physician thought he had a dilated heart, another that he had only valvular trouble, and a third was under the impression that he had prolapsus of the transverse colon and an operation was the only certain remedy. There were no complications in the way of liver trouble, lymph stasis, or indigestion, but the dietary was wrong, beginning every morning at the breakfast table. If this patient had been a woman, "go away, seek the mountains or the seashore," or "the only place for you would be a sanatorium where you can secure rest, rest, long continued and repeated," would have been the professional advice. This would have been a capital case for Dubois' "educative efforts," or Payot's "meditative reflections," because it was apparently purely psychological. On the contrary, it was purely chemical, the psychological element being directly traceable to the physiological imbalance, while the whole symptom-complex rested on the chemical deviation.

Treatment consisted in the administration of calcium iodide and phosphate, one and a quarter grains of each before and midway between meals, and as a means of conciliation, he was advised to secure a supply of effervescent sodium phosphate, to be taken in case the bowel movements were not satisfactory. A week later the patient returned highly elated, with the announcement that I had proved a true prophet, that he was another man, and he had taken the phosphate of soda but once, as the bowel movements were all that could be desired.

Mr. S., aged 36, employed in secretarial work in a large corporation, suffers from "nervousness" and cystitis, dating his indisposition back to the influenza epidemic last autumn, when he and his entire family were under the weather, although he never gave up his regular work and spent most of his time at home looking after the welfare of his family. The present weight is 156, although last summer he weighed 180 pounds; says his work bothers him, that he is unable to give it proper attention because he feels so "nervous," and getting up a dozen times at night to empty the bladder robs him of much needed rest.

Physical examination shows some intestinal indigestion, owing, probably, to an unsuitable breakfast; the heart action is "quick," the characteristic "boom" often found in such cases is absent, but the second sound is accentuated and the pulse-rate is 120 per minute. The digital tremor is marked, but the reflexes are normal.

This is almost a typical case of "The Magnesia Heart," later referred to, originally designated "The Irritable Heart of Soldiers," by DaCosta, and more recently called "Effort Syndrome," also "Neurocirculatory Asthenia." The case has been brought forward at this point for the reason that the three cases can be viewed or surveyed at the same time, since they represent the variations liable or likely to be present when calcium depletion is the dominant factor in deranging the mechanism of the nervous system. Thus, the first case is attended with complications requiring medical attention as well as dietary instruction; the second case presents what may be termed a disseminated infiltration, while in the latter case the cardiac nerve supply is impaired—at least, that is the most conspicuous feature.

Medication was first directed to the cystitis, one and a quarter grains calcium sulphide, together with one-twentieth grain strychnine arsenite, before meals, the latter being added to steady the circulation and improve the musculature of the bladder. At the end of a week the cystitis had subsided, but the tremor and rapid heart action remained unchanged, when the treatment was changed to one and a quarter grains each of calcium iodide and phosphate, this dose to be taken before and midway between meals and at bed hour. At the expiration of one week the tremor had disappeared, the heart action being reduced in frequency, 96 per minute; the patient said he felt much more comfortable, and there had been no bladder trouble, so that he secured a comfortable night's rest. Internal medication was continued and, in addition, the patient received two intravenous injections of calcium iodide, seven and one-half grains each, one week apart, with the result that at the end of three weeks the pulse-rate was 72 per minute, the heart action normal in every respect, and there were no tremors. It remains to add that the patient's weight had been reduced ten pounds during the four weeks while under treatment, due in part to the restriction of liquids with meals, and partly to alterative effect of the medication, but he said he felt much better than when his weight was 180 pounds.

Typical Chemical Deviations.—This paper has already far exceeded the limits mapped out for it, and yet I am of the opinion that it will be worth while to put on the record a limited number of ordinary clinical cases for the purpose of demonstrating "the error in the chemical exchanges of the organism," which is responsible for the so-called deficiency diseases. I had in mind to take up and present quite a collection of cases, including arthritis, paralysis from infectious embolism, arteriosclerosis, and skin diseases, the latter with especial reference to acne and psoriasis, but they must be postponed for future consideration.

Neuritis.—Mr. W., aged 46, is employed in office work in a large manufacturing plant, and although he is rather spare in build, he is not emaciated, but he has suffered from neuritis, involving the legs, for the past six years. Intestinal indigestion is pronounced and he admits that he is regularly awakened about three o'clock every morning, also that he experiences fre-

quent jactitations which wake him up—but his rest is unsatisfactory, owing to the persistent pain in the legs. During the first four years of his suffering he consulted different physicians without benefit, and for the past two years he has attended a hospital clinic regularly every week, and says he is worse than when he began, although he has had the advice of twelve different physicians. At the first visit he was asked particularly if he had pain and its location, when he stated that he had pain all the time, and located the areas.

Treatment consisted in the exhibition of calcium sulphide, together with small doses of copper arsenite, before and midway between meals, and in addition he received an intravenous injection of calcium iodide, 5 grains in 10 c.c. of sterile water. Five minutes later, he said the pain had vanished. A week later, he reported that the relief from pain had continued for about one and a half hours, but it had not returned as severe as before and he had experienced one good night's sleep. Subsequently, there was no material change in the treatment, progress was uninterrupted, and at the end of three weeks all unfavorable symptoms had disappeared and he had gained 14 pounds in weight.

Mrs. M., aged 55, housewife, has suffered for over a year from neuritis, involving the right sciatic nerve. Her husband, who is under treatment, says he wants her to go to a doctor, but she persistently refuses—and he would appreciate the courtesy if I would give him the medicine with directions. Treatment consisted in the employment of calcium phosphate and iodide, one and quarter grains of each, together, before and midway between meals. A week later, when the gentleman called, he reported that his wife had made a complete recovery.

Mrs. S., aged over 60, writes that she has had a return of the neuritis for which she was treated five years ago, but she does not feel able to make the journey to the city, and would like to have a supply of the medicine sent to her with directions. Treatment was substantially the same as that recommended above, except that the medicine was also to be taken at bedhour—six times daily.

A few days later, a letter was received, stating that the package had arrived in the morning, that she had taken the medicine during the day and experienced the first full night's rest in four months.

Neurasthenia.—Mrs. H., aged 22, weight about 100 pounds, is a semi-invalid, and has been under medical treatment for some time past, but without apparent benefit, as she still suffers from parphobia. Her husband is in France, and, of course, that is a cause for worriment, but she has other ailments—acne, eczema, dysmenorrhea, gingivitis, goiter, arthritis, scoliosis, and constipation, and practically, the entire morbid complexus is traceable to dietary deficiency. The salivary reaction is acid, the knee-jerk exaggerated, and the pulse-rate 96 per minute. Taken as a whole, this was an exceedingly unpromising case, and as she resided at some distance from the office in an adjoining State, she could not afford to make visits oftener than once a week.

Treatment consisted in the employment of the calcium iodide, five grains in solution intravenously, and along with this the internal administration of calcium iodide and phosphate, one and a quarter grains of each, to be taken together before and midway between meals—and as in all such cases, special stress was laid upon the dietary. In addition to the above, it should be stated that measures were taken to relieve the constipation, and as a result, the patient reported four days later greatly improved—the salivary reaction to litmus and the knee-jerk were normal, but the pulse-rate was 108 per minute. The treatment was varied from time to time to meet the special conditions presenting, but progress was uninterrupted—the acne and eczema disappeared, the dysmenorrhea was relieved, normal menstruation was reestablished and with it the goiter was reduced; both arthritis and gingivitis were conquered, and the discomfort incident to the scoliosis subsided. This patient came under observation April 1, treatment was discontinued early in June, about the time her husband returned from abroad, and when she called again, the latter part of July, I was able to inform her that pregnancy had taken place.

Golter.—Miss M., aged 19, weight about 100 pounds, learning the millinery business, came under treatment a year and a half ago suffering from "sore throat," but examination showed that she had enlargement of the thyroid, the affected area being confined to the right side. The history developed the fact that she had been under treatment for two years preceding for this ailment, and in the furore existing at that time for the removal of focal infection, the tonsils had been removed. As a matter of fact, removal of the tonsils had produced no apparent effect upon the thyroid enlargement, so that the "nervousness" had rather increased than diminished.

Treatment for the local irritation was followed by the usual medication, one and a quarter grains each of calcium iodide and phosphate, to be taken before and midway between meals—five times a day, special attention being directed to the dietary, by cutting out the sloppy breakfast. In the course of a few weeks all symptoms subsided and so far as I can learn there has been no return.

Judging from the numerous articles appearing in current medical literature on this subject, together with the increasing number seen on the streets and in the every-day conveyances, we are warranted in assuming that this affection is almost universal throughout the country, that it is epidemic. Instead, therefore, of advancing my personal views regarding the etiology of goiter, I prefer to quote the following extracts from a letter dated March 6, 1918, from the late Dr. W. C. Whitwell, of Salmon, Idaho, a highly respected and well-known physician in that section of the country. He says:

> The longer I practise medicine along the line of the principles laid down in your book, "The Chemic Problem in Nutrition," the more satisfaction I derive from the treatment of disease. I am simply enthusiastic over the success I am having in treating the various forms of chronic ailments. I am now treating successfully more than twenty-five cases of goiter. Usually, within ten days or two weeks the thyroid gland begins to soften and gradually reduces in size until all enlargement disappears. I first correct the digestive troubles and insist upon a suitable diet, and I depend upon calcium iodide and calcium carbonate to do the work.
>
> We have so much alkali in the soil here, which contains a large percentage of magnesium, that I feel confident this is the cause of the large increase in the number of cases of goiter. Before so much of the land was put under cultivation and the crops irrigated, we had but few cases of goiter. Now, hundreds of cases have developed within the last few years. . . . In this country especially, so many ailments are undoubtedly caused by magnesium infiltration that I hardly know of any disease that cannot be cured or greatly benefited by this line of treatment.

In a previous letter Dr. Whitwell had advised me that the water supply of the Salmon River Valley was derived from the melting snow on the western slope of the Bitter Root Mountains and "gathered" none of the essential mineral salts, the geological formation being principally slate and granite—and that seems to dispose of the antiquated theory that goiter is brought about through an excess of lime or calcium in the drinking water.

"*The Magnesia Heart* is the name I have employed provisionally to cover practically all functional derangements dependent upon disordered innervation arising from magnesium infiltration and involving the cardiac nerve mechanism, together with the disturbances due to organic changes in the circulatory apparatus from the same cause."*

Like many other names and terms, it conveys

*Quoted from "The Chemic Problem in Nutrition—Magnesium Infiltration," p. 169.

a double meaning; it denotes a physical condition, while it reflects or implies (coordinates?) a physiological or pathological significance—denotation and connotation. The name is descriptive, technically correct, and incidentally of therapeutic value, calcium being the antidote.

The present would seem to be an opportune moment for directing attention anew to this peculiar and, so far, unrecognized pathological condition which has baffled physicians for more than fifty years. In studying the symptoms, objective, subjective, and associated, I have taken every possible precaution to consider the question from every available angle and have determined definite measures for solving the occult problem—in other words, I have developed a program. Thus, problems are founded upon premises, they deal with theories; programs are determined from scientific data, they are based upon facts. The following cases are submitted in evidence:

Mr. S., aged 53, weight 125 pounds, is employed in general work about a railroad station, and has been rather debilitated for nearly a year. Medical treatment has not proven of permanent benefit and he is compelled to lay off from time to time, thinking he may be able to recuperate through rest. There is a constant feeling of depression and he is unable to stand continued exertion because of shortness of breath—even walking upstairs requires a strenuous effort. The pulse-rate is 108 per minute, small, but not receding, and it is regular. The heart action is typical of magnesium infiltration—there is a systolic "boom" with a metallic sound, the second sound of the heart being accentuated. There is some intestinal indigestion and the bowel movements are usually costive. Patient has a poor appetite and he has lost 15 or 20 pounds in weight; says he feels "nervous," and the digital tremor is well marked.

Treatment for the first week was limited to the calcium iodide and phosphate, one and a quarter grains of each together before and midway between meals, that is, five times a day; and along with this a combination to act as a mild cholagogue, special instructions being given as to the dietary. At the expiration of this period the patient reported that he was improved, not being willing to admit all of the evidences manifested from the examination—for example, the pulse-rate was reduced to 90 per minute, the characteristic systolic "boom" had disappeared and the accentuation of the second sound was greatly improved.

During the second week the same treatment was continued, and at this visit he received an intravenous injection of seven and a half grains of calcium iodide in 10 c.c. of sterile water. The injection was repeated at the beginning of the third week, and as the time had arrived for restoring the muscular tone, the treatment was modified to include calcium iodide, one and a quarter grains together with strychnine arsenite, 1-20 grain, to be taken together before each meal. At the expiration of two weeks this treatment was further modified to correct the sluggish lymphatic system, one grain of calcium sulphide being substituted for the calcium iodide.

Under this treatment the patient made rapid recovery, the pulse-rate was reduced in frequency and improved in character, the heart action was restored to normal, the appetite improved and he gained in weight, so that on the sixth visit, five weeks after beginning treatment, the original medication was resumed. Two months later this man sent his wife for treatment, and she brought a message to the effect that her husband could not be any better, and that he was able to attend to his work without difficulty and had gained considerable weight.

Mr. M., aged 51, weight 135, is engaged in the automobile business, but he says he has lost his "pep," and is unable to carry on his work to advantage, as he feels tired all the time. Examination shows the typical magnesia heart, and as a complication, there is interstitial hepatitis, and besides, there is well marked evidences of intestinal indigestion, so the vicious circle is clearly apparent.

Preliminary treatment was directed to the liver condition, special directions being given in regard to the proper diet, and the patient returned ten days later feeling better, but said he still lacked the "push" required to put the "punch" into his business. At this visit he received the intravenous injection of the calcium iodide, 5 grains in 10 c.c. of sterile water, and internally the usual medication, calcium iodide and phosphate, one and a quarter grains of each to be taken together before meals and at bed-hour. A month or six weeks later, when I met him on the street, he told me he felt all right; that the last medicine had fixed him up in good shape.

The reader who has made a critical study of the foregoing reports will observe that there are three important landmarks to be considered, namely, intestinal indigestion, a sluggish lymphatic circulation and an inactive liver, but they all hinge upon the resultant acid excess, and in most instances this will correct itself with proper attention to the dietary. While functional disorders of the heart are readily amenable to calcium medication, we must not lose sight of the fact that organic changes are likewise susceptible of improvement, as the following records will show:

M. M., aged 10, is slowly recovering from an acute "rheumatic" attack, extending over a period of six weeks, this being a recurrence of an attack a year previously, when she was confined to bed for nine weeks. This patient was a typical cereal victim, she was reduced in flesh, unable to get up in the morning for breakfast, and the joints were so involved she had to be dressed by an attendant. My attention was called to the right hand, which was swollen, stiff, and exquisitely painful, and the feet were similarly affected. The appetite was poor—for oatmeal. It should be stated that this patient had a gross mitral lesion (insufficiency), as a result of the original attack.

Preliminary treatment consisted in the administratino of calcium sulphide, one grain every two hours, and a hot Epsom salt bath to be given at bed-hour. The patient was better the next day, when the treatment was changed to calcium iodide and phosphate, one and a quarter grains of each together before and midway between meals and at bed-hour—six times a day. Improvement was immediate and marked; three days after treatment was begun the little patient got up of her own accord, dressed herself and came down to breakfast, and a month later the mitral murmur was scarcely perceptible, since which time treatment has been discontinued. Seen on the street, romping and playing with other children, this patient has apparently made a perfect recovery. I met the parents on the train one day and they told me the little girl had an acute attack of ptomaine poisoning, when they called a local physician, who pronounced her perfectly sound.

Mr. M., aged 73, weight 162 pounds, is employed in one of the municipal supply sections, where he collects materials and fills orders, the room in which he works being under ground and usually kept very hot. Says he has been in failing health for some time past, but a vacation of two weeks last summer did him a great deal of good. Thinks his present difficulty is serious, as he cannot walk far, not more than across the street, without stopping to get his wind, and frequently he has to sit down on the pavement. His memory is failing, he is unable to recall where he has laid things, and not infrequently he gets lost himself, thus showing defective orientation. Neuritis, involving the right musculospiral nerve, seriously interferes with his rest, and he also says his appetite has been very poor for a long time, although he has not lost much weight.

Examination shows acid salivary reaction to litmus, knee-jerk impaired (limited), well-marked intestinal indigestion; the heart is what DaCosta termed "tumultuous," and the pulse-rate is not countable, there

being but one full beat in five to eight in time—it was regularly irregular.

Technically, this patient was suffering from arteriosclerosis, and especially hardening of the coronary arteries, which interfered with the nutrition of the heart, and in addition there were evidences of aortic stenosis.

Treatment, begun September 19, 1919, included calcium iodide, seven and a half grains intravenously, the calcium iodide and phosphate to be taken internally, one and a quarter grains of each together before and midway between meals and at bed-hour, special directions being given as to the dietary. Internal medication was continued, the injections being repeated on the 27th and on October 2, 7 and 11, when the pulse-rate was found to be 84 per minute, although one-half or more of the beats were rather indistinct. The knee-jerk was still impaired, but the man walked without difficulty, and he expressed himself as being much gratified because of the improved mental coordination. This treatment was slightly modified; to improve the muscular tone and at the same time stimulate the lymph-glandular apparatus, the patient took one-twentieth grain strychnine arsenite together with one grain calcium sulphide before meals, and seemed to be making good headway, but unfortunately he had a bad cold during the last week in October. The cold responded to treatment, so that the latter medication was resumed early in November—without the injections—and on November 11, at the date of writing, the patient's condition is nearly normal. The neuritis has disappeared, the patient has a good appetite, the bowels are regular, and he also sleeps well; he has no trouble whatever in walking, even in going up a rather steep incline; the pulse-rate is fairly regular at 78 per minute, and it does not intermit.

Mr. M., aged 29, weight 140 pounds and well built, says he has a languid feeling which he is unable to throw off, and for a year past he has felt an indisposition to exert himself. He claims it is not due to laziness, because he has always been active and energetic. His work, as an office employee, does not afford much outdoor exercise; he has no recollection of any rheumatic symptoms, nor does he recall any unusual effort which would be likely or liable to cause heart trouble, but the indisposition may be traced to valvular incoordination. The salivary reaction is alkaline, the knee-jerk limited, showing impairment in nerve conduction, and the pulse-rate is 84 per minute.

Treatment included regulation of the dietary, and for medication calcium iodide and phosphate, one and a quarter grains of each before and midway between meals—five times a day. The patient reported at the office seven days later with the pulse rate 78 per minute, no valvular trouble, and he said his appetite had improved, that he slept well and felt again like his former self; what he wanted now was to go ahead and get things done.

Mrs. S., aged 70 plus, rather light build, not employed, has suffered for many years from cardiac embarrassment. Says she can hear the "squeak" in her left ear when she lies down. In addition to this she has Raynaud's disease, affecting the middle finger of the left hand. This has been present for several years and it is so long since she had rheumatism that she cannot remember. This patient has consulted quite a number of physicians within the past ten years, and has been under treatment long enough to give many of them a chance to demonstrate the efficiency of medical science, but in no instance has any improvement followed, immediate or remote. She thinks that usually digitalis was prescribed, because she has had it explained to her that digitalis was the only available remedy, and she says all the medicines taken tasted alike. Fortunately, she escaped with her life.

Treatment consisted in the administration of calcium phosphate and iodide, one and a quarter grains of each before and midway between meals and at bed-hour. A week later the patient reported that she could walk up an incline without difficulty, that the numbness in the finger had mostly disappeared within the preceding few days, while the mitral insufficiency had practically subsided. The pulse-rate was 66 per minute.

1024 Walnut Street.

BLOOD TRANSFUSION IN OBSTETRICS.*

By J. R. LOSEE, M.D.,
NEW YORK.
PATHOLOGIST TO THE LYING-IN-HOSPITAL.

Since the advent of the various methods of indirect blood transfusion it has been suggested at one stage or another for almost all the ills that man is heir to. There are, however, certain definite indications for its use and the foremost of these is to supply blood lost after acute hemorrhage. In no branch of the practice of medicine do large hemorrhages occur more often than in an active obstetrical practice and I believe it is considered one of the most frequent causes of death in pregnancy and labor. I grant that serious hemorrhage occurs very rarely in the practice of the well trained and careful obstetrician but this type of practitioner is still in the minority and emergencies are quite occasionally admitted to the hospitals intra-partum and post-partum in a serious condition from loss of blood. Now if these patients can be carried through the critical period of air hunger and collapse by the prompt administration of 500 to 1000 c.c. of blood, complete recovery will be assured in most instances.

The introduction of the indirect technique and of the more rapid method of determining the compatibility of the donor's blood for the recipient has made the operation of blood transfusion more accessible for emergencies and absolutely without danger of accident. The infusion of normal saline in hemorrhage is quite temporary in its effect because it soon diffuses through the vessel walls leaving the circulation again depleted, whereas blood cells and plasma when injected, remain in the vessels and no doubt begin at once to carry on their function just as if they had not been transferred. Muscilage of acacia solution has been administered intravenously for hemorrhage or shock on the theory that it remained in the vessels and did not immediately diffuse into the tissues like normal saline. More careful inquiry, however, has shown that the effects and results have been rather unsatisfactory and in some cases disastrous as many of us would expect.

Before there was any knowledge of the presence of iso-agglutinins or isohemolysins in human blood certain definite clinical reactions occasionally took place in the patient during transfusion which were characterized by severe symptoms and sometimes death. The cause of these reactions has been shown to be due to the presence of isohemolysins or iso-agglutinins or both in the plasma of the recipient and donor. Until recently the technique for the identification of isohemolysins and isoagglutinins *in vitro* has taken at least three hours and often longer and although in 1909 Epstein[1] and Ottenberg simplified this method somewhat it was still unsuitable for emergency work. Brem[2] following Moss's hypothesis that isohemolysis is probably always preceded or accompanied by iso-agglutination both in health and disease, developed a technique for the identification of iso-agglutinins by microscopical examination which can be done in less than one-half hour. By this method he places all individuals into four groups according to the Moss classification. Since Brem's publication Moss[3] has developed an

*Read at a meeting of the Society of the Sloane Hospital for Women, October 24, 1919.

even more rapid method and now there is no emergency so great but that the operator can be reasonably assured that he is transfusing a patient with campatible blood. By some observers an additional test for isohemolysins is also required, but it has been my observation in performing comparative tests that both methods have coincided exactly in the examination of patients acutely ill from hemorrhage and even in toxemia. On the other hand inasmuch as isohemolysis is said to be a pathological phenomenon, it is well to make the additional test in patients suffering from chronic diseases.

Donors.—As far as possible donors should be strong, healthy, muscular individuals without a nervous temperament, otherwise the operation may be terminated earlier than is desired on account of an attack of syncope. A Wassermann test and a physical examination are made on all donors before each transfusion regardless of the fact that they have been examined on previous occasions. Syphilis has been transmitted more than once in this way and in the examination of 150 donors I have obtained six strongly positive Wassermann reactions.

It has been the practice of the Laboratory during the past three years to have on file a number of donors in each group and when the emergency arises the patient is grouped and a suitable donor is reached by telephone or telegraph. On his arrival he is again tested for iso-agglutinins and a Wassermann is made if time permits. Very often in the hospital service patients are admitted in a serious condition after hemorrhage and prompt action must be taken. The patient, her friends, and hospital porters are grouped while the necessary preparations are being made for the operation. As far as possible only individuals of the same group are transfused and when this cannot be done a group four donor is selected. Inasmuch as the serum of group four agglutinates the cells of groups 1, 2, and 3, and since it has been shown by Ottenberg[4] that the serum of the donor is so diluted by the serum of the patient that no agglutination takes place, group four has been used as the universal donor in emergencies without reactions, for the cells of group four are not agglutinated by the serum of any other group. No doubt this fact is largely responsible for the few reactions which formerly took place when no preliminary tests were made. The amount of blood taken from the donor depends upon the weight and condition of the patient, the weight of the donor and the indication for which the operation is performed. It is always well to watch the donor of such symptoms as yawning, sweating, and a lowering or elevation of the pulse rate, as under such conditions it is advisable to stop. Occasionally a donor may go into collapse from which he recovers in a short time under appropriate treatment but this is not a pleasant feature and can always be avoided by carefully observing him when the amount of blood transfused approaches 1000 c.c. At the present time professional donors are repeatedly submitting themselves for transfusion when they are physically unfit, but their condition can be readily determined by reading the hemoglobin and by bleeding them into a test tube and estimating the relative volume of solid and fluid constituents of the blood. The blood of one who has been repeatedly bled and is suffering from secondary anemia shows a much larger proportion of serum than cells and this type would not be the most beneficial.

Methods.—Physicians interested in transfusion differ widely in their opinions as to the relative value of modified and unmodified blood. The citrate method has gained its popularity on account of the facility with which it is performed, but there is no reason to believe that it is as beneficial to the patient as the unmodified blood which is not subjected to any chemical change and which is out of the body such a short time. It is indeed quite true that citrated blood is entirely efficient in patients suffering from acute hemorrhage when volume only is needed, but with patients who have had a severe anemia for sometime or some form of toxemia and are in poor physical condition, the method which will accomplish the best results with the least possible tax on the already poorly functionating organs of the patient is the one to select. The syringe-cannula method, the Unger method, or the paraffin-tube method of Kimptom and Brown may be used at the discretion of the operator for the transfer of unmodified blood from the donor to the recipient. The selection often depends upon the means at hand and whenever possible unmodified blood is to be preferred because it is the best method we have of injecting the same kind of blood that is already circulating in the vessels of the recipient.

Reactions.—Drinker and Brittingham[6] have reported several transfusions using different methods and make the impartial statement that it would seem that both the syringe cannula and the paraffin-tube methods offer fewer reactions than the citrate. A severe reaction with all the classical symptoms of hemolysis occurred early in my experience after an emergency transfusion, but before which no examination for isohemolysins or iso-agglutinins was made. In no other case has there been any reaction due to hemolysis or agglutination and I attribute this to the care with which the donors have been selected. I am surprised after ready the protocols of some of the later articles in which serious reactions are described, for these probably have been due to careless laboratory work and a lack of knowledge of the serious consequences which happen under such conditions. A few mild reactions characterized by slight chill and rise in temperature have occurred in a small percentage of the series but these were all transitory and passed off in twelve hours. The more perfect the technique of the syringe-cannula method the less often will these so-called mild reactions occur. The care and thorough washing of the syringes, the filling and emptying of the syringes and the length of time the blood is outside of the body are small details which if not carried out may give rise to these reactions and establish a platelet and anaphylotoxin hypothesis.

Report of Cases.—Since the introduction of indirect transfusion I have performed the operation 78 times on 70 patients suffering from the complications of labor. Sixty-one were done by the syringe-cannula method and seventeen by the citrate method. There were fourteen deaths in this series and all but one was undoubtedly due to the disease from which the patient was suffering. The latter, which may or may not have been due to transfusion, occurred early in the series, was an emergency, and no preliminary tests were made.

I have classified the indications for transfusion in obstetrical cases into four groups. There were thirty patients on whom the operation was performed for hemorrhage or hemorrhage and shock, twenty-nine who were suffering from post-partum hemorrhage and localized pelvic sepsis, seven who had either bacteriemia, septic thrombophlebitis of the pelvic veins, or general peritonitis, and four with toxemia of pregnancy of the pernicious vomiting type.

Of the thirty patients suffering from acute hemorrhage due either to placenta previa, post-partum hemorrhage, premature separation of the placenta, ruptured ectopic, or ruptured uterus, thirty-two transfusions were performed and six patients died. Many of these patients were in exceedingly poor shape and no doubt would have died in a few minutes had they not received a large quantity of blood intravenously. I recall a case of spontaneous rupture of the uterus in the fifth month who, when the transfusion was started, was breathing six to eight per minute and no blood was present in the median basilic veins when the cannula was inserted. After the injection of 1250 c.c. the color and pulse returned, breathing became more regular and recovery was uninterrupted. Another case with post-partum hemorrhage and inversion of the uterus was breathing occasionally when the operation was started and after 200 c.c. were injected breathing ceased and the house surgeon reported no heart sounds audible with the stethoscope. Transfusion was continued on the grounds that the heart muscle was still contracting weakly and probably needed a larger volume of fluid. After 400 c.c. were injected the heart sounds were again heard and breathing was reestablished. At this stage in the operation the donor, who was the husband, and in poor physical condition, fainted and the infusion was carried on with normal saline. This procedure kept the patient alive until another donor was secured three hours later and a second transfusion of 800 c.c. carried the patient out of the immediate danger of death and she was discharged in three weeks. A case of placenta previa and another of ruptured ectopic were also in the air hunger stage when they were relieved by the intravenous administration of blood.

I mention these few cases merely to show that they were undoubtedly snatched from the jaws of death by blood transfusion. Many others in this class were also in a serious condition and whether they would have recovered without transfusion it is impossible to say. No doubt some would and others would not have done so, but why wait to perform the operation until the patient is dead or nearly dead, for it is a harmless operation with the present technique. Williams[6] has recently informed us of the large amount of blood the lying-in woman can lose, but patients differ and we are not always sure that we are dealing with a patient that can lose 2400 c.c. of blood without a serious result.

I have occasionally seen patients suffering from ruptured ectopic or rupture of the uterus who were either bleeding very little or had entirely stopped, begin bleeding again after the transfusion of 500 to 600 c.c. of blood; therefore it is advisable either to tie off the bleeding points, or be prepared to do so before the transfusion is begun.

There were twenty-nine patients with anemia secondary to post-partum hemorrhage and localized pelvic sepsis on whom thirty transfusions were done. They all completely recovered although some of them seemed critically ill on admission. By localized sepsis I refer to all infections of the genital tract from lacerations of the vagina to the pelvic peritoneum.

Some of these patients were admitttd with red blood cells as low as 1,200,000 and a hemoglobin of 20 per cent, while one had red blood cells numbering 500,000, 10 per cent hemoglobin, 31,000 leucocytes with 89 per cent polynuclears. This patient was admitted sixteen days post-partum with a history of retained placenta and a curettage six days after delivery. She had continued to bleed during the puerperium, had some fever and on the fifteenth day there was a chill and sudden rise of temperature to 104°. On admission she was in delirium, temperature of 104°, rapid weak pulse, marked subinvolution of the uterus and the outlook was unfavorable. A blood culture was taken at once and reported sterile after seventy-two hours. A second blood culture was also sterile. Two hours after admission a citrate transfusion of 950 c.c. of blood was made from two relatives who were at hand and within one hour the temperature had risen to 107° with a chill. This temperature receded to 102° in five hours and the following day the geneneral condition of the patient was somewhat improved with a blood count of 1,460,000 red cells, 20 per cent hemoglobin, 21,000 leucocytes, and 91 per cent polynuclears. On the second day after transfusion it was noticed that the blood count was again falling and there was a continued rise of temperature with chill. Another transfusion of 800 c.c. of unmodified blood was given without reaction and on the sixth day after admission the temperature reached 102° and remained there with slight fluctuations for the following three weeks when it suddenly reached normal. Three days after the second transfusion the red blood cells were 2,060,000 25 per cent hemoglobin, 15,000 leucocytes, with 85 per cent polynuclears. Thereafter the blood count was never less than two million cells and she was discharged fifty days after admission with 2,900,000 erythrocytes and 25 per cent hemoglobin. Transfusion improves the general condition of these patients and places them in a position to combat the infection; and whereas in this type of case the procedure is not life saving, although it appears to be, it does shorten convalescence, it has some economic value and it is rational therapeutics.

The treatment of general sepsis (bacteriemia and septic thrombophlebitis of the pelvis veins) by blood transfusion has again been mentioned in a recent periodical. This treatment has been tried before on many occasions even to the extent of immunizing a donor with autogeneous vaccines but with almost universally poor results. Other than acting as a supportive measure there are no scientific principles as a basis for such treatment because human plasma is very slightly, if at all, bactericidal. Patients with post-partum bacteriemia due to hemolytic streptococcus or *staphlococcus aureus* are suffering from a fulminating infection and in the majority of instances succumb to the disease in from seven to ten days.

Very occasionally a patient is seen with a blood stream infection due to a moderately avirulent organism, or a patient may have considerable natural immunity and she recovers under the usual treatment after a prolonged clinical course. I have transfused only two cases of streptococcemia and both promptly died in a few days, therefore my experience has been limited.

In septic thrombophlebitis of the pelvic veins without metastases we have more opportunity to try the effect of blood transfusion as a supportive measure for they usually live longer than the cases of bacteriemia; but even here we are not directly combating the infection. I recall two cases in this group, one of which died and the other was associated with a transitory bacteriemia and recovered in six weeks after three transfusions at weekly intervals. Again my short experience does not permit me to make a definite statement as to the results which may be obtained.

Four cases of toxemia of pregnancy of the pernicious vomiting type have been transfused with two deaths but here again it is only a supportive measure.

Hemorrhage of the new-born is a disease which is seen in obstetrical practice and which calls for prompt treatment. Blood transfusion is the method of treatment because it not only checks the bleeding by supplying the organism with all the substances of the plasma, cells and platelets but in the more serious cases it also treats the anemia. Here the operator is confronted by considerable mechanical difficulty on account of the size of the superficial veins.

It is true that the superior longitudinal sinus is a popular route for intravenous administration of medication in infants, but it is also very easy to puncture its side walls and the blood is forced beneath the dura and therefore it is not without danger. With due care, however, and the use of small instruments, the median basilic and cephalic veins can be successfully entered with much less danger of injury to the infant.

Conclusions.—1. Serious hemorrhage complicating pregnancy and labor has been successfully treated by indirect blood transfusion.

2. In anemia, secondary to post-partum hemorrhage and pelvic sepsis, transfusion is definitely indicated and produces satisfactory results but it has little or no effect on patients suffering from bacteriemia or septic thrombophlebitis.

3. Inasmuch as indirect blood transfusion in obstetrics is often a life-saving procedure obstetrical institutions should be prepared to perform the operation instantly and at any time.

REMEDIAL MEASURES CONSERVATIVE IN MOST ACUTE INFECTIOUS DISEASES;

IN PARTICULAR FOR ADULTS AND DURING INFLUENZA.

By J. MADISON TAYLOR, A.B., M.D.

PHILADELPHIA, PA.

PROFESSOR OF PHYSICAL THERAPEUTICS AND DIETETICS, MEDICAL DEPARTMENT, TEMPLE UNIVERSITY.

THE urgent dangers during acute infectious disease would seem to be, in adults especially, proportional to the character and force of their mental reactions. Perils due to fluctuations in the affective realm, the impulses, feelings, emotions, preferences, conceptions of duty, vary as to the form which these take. The element of fear or of indifference deserves the first consideration; next the obscuring effects of environmental influences, of family urging, of habit, of custom, of tradition, and of example.

One phenomenon, characteristic of all acute febrile processes and one too often disregarded, is disturbance of self possession, sound reasoning, or judgment. The mind is then at the least, cloudy, the sense of values, of proportion, of nice discrimination, is uniformly impaired. A patient when confronted with the need for surrendering self guidance is then rendered irritable, recalcitrant, obstinate, unreasonable. We can never be sure whether a mild delirium has begun, or enough to compromise judiciality.

To what extent fear, anxiety, suspense, tend to lower resistance can never be known in advance, but the whole history of clinical medicine is full of graphic instances of individual and group fatalities due to anxiety depression. This is especially cogent during epidemics.

In the majority of those in whom an acute infection is recognized or adequately inferred, the adviser is met by an overmastering sense of duty which drives them to rebel, to refuse to believe the patent facts, especially while no sense of weakness is felt. Of course such persons demand to remain at the post of duty. We physicians ourselves do this; our sense of obligation to duty is that of a rescuer of others. We can only be rescued through a combination of mass persuasion and force. Many of us have done our most important work in saving lives while our own temperature was higher than that of any case we met. I recall myself disregarding recurrences of chills, of the characteristic sense of detachment, of vague miseries and, when intercepted by a vigilant young medical protégé, my temperature curve was at the apex before being forced to bed. I was then, and have several times been similarly, unable to realize my state. Many physicians thus come to die in their tracks, due chiefly to our delusion that *we* know when an illness is present. For ourselves we don't.

A professional colleague in my office during a "flu" epidemic upon my remarking that he was looking ill and demanding to take his temperature and to examine him, it was found to be 105°, one lung being solid, and the other nearly solid, with pneumonia. Even then it was some job to get him to bed. If doctors can be so pardonably obstinate or reckless when their own minds are acutely out of commission, how much more pitiful is the delu-

sion of a fever-beclouded layman. Of course the Captain of Industry who is absolutely well *may* admit this point academically, but when he is infected his habit of domination leads him to then rebel.

How often during an epidemic of (say) influenza do we hear substantially this reply: "Of course *you* cannot understand (*sic!*) but it is quite imperative that *I* must have at least two or three days to fulfill this or that *really important* obligation, to finish this or that task; after that I will consider going to bed if necessary." If there is one fact we know to be most near a fundamental truth it is that protracted exertions during the first two or three critical days of an infection, of rapid weakening of the defense energies, encourages depletion of the factors of safety, precipitates complications, and often seals one's fate.

The physician should preach in season and out of season till it becomes an automatic reaction: the most economic act of one's life is to go to bed at once at the onset of an infection—no appeals so much as *heard*.* Thus we may assume that the crux of conservation is instantaneous rest in bed, also equally that the utmost caution and obedience shall be maintained during the convalescence, when the heart muscle is depleted, the energies all confused, the repair powers out of gear.

The next precaution is to revise and rectify dominantly the false mental reactions of the domestic circle. All sorts of dangerous and erroneous habit reactions or complexes are exhibited by members of the family or by associates. These are the products of half baked notions on hygiene, based on sound rules misinterpreted. The tendency is for sympathetic or meddlesome friends to offer all sorts of fussy, silly doings, takings of drugs, of foods "to keep the strength up," and numberless futilities, many of which are positively dangerous.

One of these false mental (fool) reactions is to give a purgative, just when the gastrointestinal nerves and mucosa are most sensitive, the normal defenses most disordered, the structures most vulnerable. The surgeon has had a recent life-saving change of heart. If healthy rabbits, guinea pigs, and other laboratory prey show grave irritations of the intestines after purging, should not our patient, all upset during the first phase of self readjustment to infectious agencies, be rescued from a purge? To be sure many who take them do survive; and then again many don't.

An enema, or colon irrigation would serve all, or most, indications, especially if to it is added a little salt and more soda, in order to furnish an alkali for absorption while the alkaline content of the blood is disturbed. A full irrigation is advisable immediately, and a smaller one on each following day for two or three days. Diuresis will be greatly assisted, acid infarcts in the kidney being washed out. (See Martin H. Fischer.) As to calomel or a mercurial, that is a wholly different matter, one for the physician to decide. Small doses of calomel enhance oxidation in the intestinal juices.

The third precaution I submit will be stoutly opposed by the family. That is, give no food for at least three days—except water and fresh fruit juices, orange or lemon or apple, etc. There is then rarely appetite; there is *never a real hunger*, or an organic *need* for food. This anorexia is nature's notice to quit, to allow the organs of digestion and especially the mechanisms of elaboration and metabolism, a *chance to rest*. Let them alone; aid them to extrude all the half elaborated, the readily vitiated food elements and permit secondary products the opportunity to withdraw quietly. Do not burden these mechanisms with fresh burdens; remove the load from an overburdened organism. Release the oxygenating mechanisms from the task of working overtime to burn up *newly introduced* complex nutritive substances.

Finally let me commend a measure which, while it has not received the endorsement of many authorities, is employed with deep satisfaction by a multitude of those best friends of humanity, who are too busy to tell in print of their convictions, *i.e.* country doctors, nurses, self constituted ministers of health in small communities, and others whose mental reactions are sound and fortified by experience. This remedy is heat and pressure applied to the whole back.

It may count for something to relate personal experiences in many hundreds of cases, results to be obtained by no other means known to me; at least none are so readily secured by agencies so simple and so available. Heat, *along with graduated and distributed pressure*, over the surface of the back, will relieve a host of vague as well as harassing discomforts, stresses, distresses, miseries, pains, aches, tendernesses, tonic protective spasms, rigidities, and the like deterrents to serenity, ease, or sleep. It will do much more. It will stimulate vasorelaxation, hence tend to induce sweating when the skin reaction is suspended. This vasorelaxation induces varied and most beneficial effects.

This means of releasing stress, pain, vasohypertonicity will prove so wholly satisfactory that any one who will give it a fair trial must concur in my enthusiasm. Of course it must be well done; it is something of an art, which even every expert blanchisseuse (washerwoman) does not possess. I claim some personal skill and insist on myelf applying the (not too) hot flatiron, over a thick bath towel (or other fabric) *dry* in some cases, *damp* in others, *i.e.* in order to excite the sweat glands. If space permitted I should like to elaborate a few artistic points.*

In addition to the explanation therein given of the vasomotor and other reactions, let me refer here to statements by Dr. C. T. Sharpe in a paper on "Edema of the Brain in the Infectious Diseases," especially the "Interrelationships Between Cutaneous and Spinal Pressure." In speaking of the cerebral type of the infectious diseases, he cites his earlier observations which tended to show the possibility of the involvement of the cerebro-

*It is most unfortuate—for the patient—that the physician is endowed with no adequate authority. Upon the slightest offense he can be dismissed. If he had mandatory powers he could multiply his life-saving efficacy a hundredfold. This deficit in potential is mainly due to the idiotic custom of paying him by the visit. Most patients gloat on saving a dollar.

*See article by author in *Boston Medical and Surgical Journal*, October 9, 1919, "Cardiovascular Regulation by Other Means than Drugs."

spinal axis and the nervous system generally, as opposed to the viscera and the skin, and remarks "that in the infections and contagions, the central nervous system may be involved by the bacteria or their toxins to such an extent that this involvement may far outweigh and mask the involvement of the viscera and the skin. It may be that we are justified to go farther and state that the primary involvement may be that of the central nervous system and that when such primary involvement does occur the other manifestations may be wanting or so atypical as to be deceptive. In scarlet fever, measles, and diphtheria, edema of the brain exists in some cases to a very marked degree," And later, "If the cerebrospinal pressure is high, so high that a child lies in an almost comatose condition with his eyes rolled up out of sight and is only partially relieved by lumbar puncture, and there should occur an intense urticarial rash covering the whole body followed by a restoration of the cerebral functions to normal within a few hours; if a temperature of 103° F. or higher should at the same time fall within twelve hours or less to normal and remain down thereafter; and if this phenomenon has been observed not once but many times, sufficiently often, in fact, to enable one to prognosticate the course of the temperature and the end—results of the illness every time—is one justified in stating that there is a balance of pressure between the two, the increase of one automatically reducing the other and favoring the absorption of the exudate? The brain and the skin are developed from the ectoderm. Sweating was a notable feature of some patients, and was particularly marked in several very severe cases. The sweat glands act as safety valves. If, then, the rash strikes in, as it was expressed by our grandmothers, we would expect to find this edema in that portion of the body that has an interrelationship as to pressure with the skin."

Let me outline again certain recommendations I offered and sent to the newspapers, at the outbreak of the influenza epidemic in 1918, with the statement that much could be done by an informed laity to aid and abet the work of the physician. The suggestion was made that many persons would be thus encouraged to consult a physician much earlier and obey him more implicitly. These simple hints were copied widely and apparently did good, possibly some lives were saved thereby. Anyhow the efforts of physicians were thus supplemented.

In the case of influenza, poliomyelitis, and some other epidemic and exanthematic diseases, no uniformity has been reached as to the drugs to be relied on, except as modifying symptoms. Fair agreement should be made as to rational procedures, items of conduct, cooperation, and personal regulation. They are based on just as much *science*, physiological, pathological and therapeutic certitude, as is the action of drugs.

The evidence seems to show that closely similar toxic manifestations occur in all acute infections, however much they may vary in detail. Let me mention here as a powerful evidence of the value of conservative measures one instance of phenomenal results from military discipline where prompt isolation, strict quarantine, and systematized and adequate measures from start to finish were followed and *no death occurred among* 3,500 *young men* of a students' army and navy corps. At Princeton, New Jersey, the command was vested in Admiral C. F. Goodrich. Under him were the army unit, his own naval unit, a civilian group, an aviation school, etc, a total of 3,500 young men. Briefly, the Admiral adopted the plan of strict vigilance on the part of his surgeons, the immediate isolation at the athletic field, surrounded by a high fence, guarded by sentries, and equipped with ample beds, etc., the regular "training quarters." Here much the same precautions were employed as I recommend.

Restatement of Points.—1. In every instance of infection individuals may safely be assumed to be no longer capable of judging for themselves what to do and not to do. In many instances (I think most) the mind is clouded and confusion states pass readily into a mild delirium. Hence gentle coercion as to conduct is in order. 'Tis a thousand pities the physician is not endowed with mandatory powers.

2. Absolute rest in bed (isolation preferred), at the earliest moment the malady can be recognized or reasonably inferred, and maintained so long as may be deemed necessary.

3. Return to activities should be made with extreme care in view of the shocks suffered by the control mechanisms, especially shown by the weakened myocardium and other vital structures.

4. For the first two or three days it is best to give no food but plenty of water, preferably hot, adding some sodium bicarbonate and salt (20 grains of each), to eight ounces water, weak tea or coffee if craved, and plenty of fruit juices (for the contained alkaline carbonates and vitamines), also fresh clam or oyster juice (for the lime they contain). Cold water or even ice may be craved when the temperature is high. Usually there is no real hunger in these early days, a plain indication that the digestive tract, liver, and other eliminating organs need complete rest, also the laboring heart, blood vessels, and kidneys demand relief from work. The primæviæ should be relieved of labor, so that the products of fermentation and of putrefaction, and body formed toxins and all the coarser food or chemical residua be allowed to pass out expeditiously.

Abstention from food promotes changes of body wastes into the more eliminable forms of end products. In short, a brief fast tends to expedite "the cleaning up of the house of man." The circulatory reflexes deserve to be no longer excited by aiding in active nutritive processes. The burden upon the cardiovascular renal cycle is reduced to safe proportions. A tendency is encouraged for the whole organism to sink into a serene, comfortable state of ease, tranquillity, peace. So soon as the natural demands for food return they may be supplied. Even then care should be exercised so long as the febrile process continues high, in order that this hunger be not confused with the cravings of suggestion, of habit, or taste or whim. The foods when allowed should be supplied with due regard to whatsoever organic disturbances are prominent or determinable. Uranalyses and blood studies will go far toward making these clear.

5. No purgatives should be given, not even

salines which greatly irritate the intestinal and renal mucosæ. Calomel in broken doses may be of great use to stimulate oxidation. An enema or colon irrigation, however, is desirable every day for three or four days and then at intervals till full convalescense.

This enema should contain salt (NaCl, gr.xxx) and sodium bicarbonate (ʒi) to the pint in order to act as an alkaline diuretic. The blood in infections tends to lose its alkaline equilibrium, to become acid, hence the alkaline enema is distinctly beneficial, and the free diuresis produced gives much comfort.

6. Sweating, unless active, should be encouraged by simple means. The measure which serves me best is to lay the patient face down, place a slightly damp (not wet) bath towel over the whole back and pass a moderately hot flatiron up and down for five or eight minutes till the skin reacts and the whole body sweats freely. Should the hot iron prove suddenly painful lift the towel instantly from the surface and lay it down again and proceed, keeping the iron in motion and not allowing it to rest on any one locality but be kept moving about.

This ironing will usually relieve all backache, and other aches, belly aches, many headaches, chest pains, also reduce dyspnea, cough, throat tickling, etc. It also promotes tranquillity so that thereafter the patient can take a nap immediately. The throat and nose demand local treatment also, especially where there is cough.

7. Diverse symptoms accompany the infection, due to a multiplicity of disturbances, most of which are due to toxic irritations of the more delicate reflexes. Among these are tonic spasm in muscles, the unstriped as well as the coarser, especially in the static muscles of the back, limbs, scalp, or eyeballs. These may require medication, but in my experience most of them can be better disposed of by the use of heat or cold, of tactile applications, manipulations directed to nerve points or to the erector-spinæ muscles, the paravertebral structures, etc. This is notably true to relieve localized distresses, gaseous distention, tonic protective spasm, cramps in the hollow viscera, even of the heart and great vessels, or kidneys or uterus or testicles. The centers in the back offer a plain, definite surface for applying curative touches, by any one who knows how. (Those who don't had better learn or perhaps their reliance may be upon drugs. These are liable to fail, not to react as expected. Biokinitic remedies are surer and safer.*)

8. At the oncoming of a pneumonitis rest must be immediate and absolute; no tampering, no postponing, no modifying. A chill—other than that inevitable to exposure to sudden or unusual cold—portends some serious perturbation in functional balance; it must not be disregarded. A chill or chilliness is the characteristic portent of pneumonitis. Any one who experiences a chill disregards it, and survives (as I did), will have learned a valuable lesson. Rest must be complete. *During the active stages of a pneumonitis, no sitting up should be allowed, not even for examination.* I have seen men otherwise perfectly vigorous and healthy die from rebelliously making this exertion alone.

Posture is most significant in pneumonitis. The side chiefly affected is down and the competent side up, but this attitude should be changed occasionally for short periods. Lying constantly on the back should be discouraged. The *head* of the patient (protected) should be toward the light but *not facing a window.* Constant glare in the eyes is a severe strain. Only in this attitude and with the eyes protected, can the patient be so free to assume conservative postures. The reasons for avoiding upright or sitting postures are many and absolute and based on biophysics. Among them are the condition of the blood, which is overviscid; stagnation in and extra weight of the viscera, hence the drag caused by dependent overloaded and weakened organs upon the diaphragm; irritation of the splanchnic branches of the vagus; the weakened heart (myocardium) being seriously overburdened, peripheral resistance is often so compromised as to inhibit circulatory distribution.

9. Revulsion is of great importance, as all experienced clinicians know through a certain and reliable knowledge. The long discarded poultice or mustard pack served excellent purposes, but better means are now at hand. The best form, in my judgment, is ironing the back. In pneumonitis there is often much disturbance of the vasomotor system and sweat glands.

Dry cupping is efficacious and strongly endorsed. A much simpler method of achieving local hyperemia and revulsion is by subdermal traction, a lifting and pulling of the skin on the back by the hand from the underlying structures all up and down the back, especially from the fourth to the ninth thoracic vertebræ, and all over the lateral areas, stimulating subsidiary sympathetic (vasomotor) subcenters. This, while painful at first, soon ceases to be so, and can be repeated to advantage every hour or two by the nurse. The effects are just as emphatic as those of Bier's hyperemic cupping. It will often promptly reduce or check cough.

10. When mental confusion is recognized, then quieting measures are required. One of the most efficacious measures is the neutral immersion bath, or tepid soaking in water at 100° F. for twenty minutes or so long as comfortable. I believe many a life would be saved by observing so simple a measure, accompanied by a saline enema and hot drinks; this will transcend any sedative medicament. A chill is due to a profound perturbation of function, and calls imperatively for external heat, and the best and most available relief is a warm full bath or hot foot bath. Trypsin, in order to carry on oxidation, must be fortified by heat. When delirium persists with low temperature repeated warm or hot affusions are indicated, tepid sponging or hot packs or the heat and pressure of the flatiron over a damp blanket along the bare back. The violently delirious, struggling patient often dies, and this fatal result in pneumonitis is more often than not due to the intense overexertion. Thus psychogenic perturbation comes to be recognized as of the deepest significance and peril.

This significant fact should always be considered,

*See article by author, "Backache or Tenderness," *Int. Clinics*, vol. 1, series 29, March, 1919.

that the sodium chloride loss in pneumonitis is enormous (often 50 ounces in 24 hours) and should be resupplied. This is best done by adding salt in the proportion of normal salt solution to all drinks at all times.

11. Convalescence is a most critical period in which the whole of previous wisdom (or luck) may be nullified. The fatalities or secondary decrepitudes or disasters are, in my opinion, due chiefly to errors committed by the patient, in which the adviser may be equally at fault.

The patient must be made to realize that expert guidance during convalescence is the prime duty of the medical adviser, and the obligation of the patient is to cooperate faithfully and consistently.

1504 Pine Street.

PROGNOSIS IN PULMONARY TUBERCULOSIS.*

By ALFRED HENRY, M.D.,
INDIANAPOLIS, IND.

In discussing this subject I have no intention of enlightening anybody regarding any scientific phase of the field. However, there are scientific aspects which are interesting as well as worth knowing. For instance, there is a nuclear count originated by Arneth which is very valuable in prognosticating pulmonary tuberculosis. We know there are on an average about so many nuclei in white blood cells. Some have one, others two, while many have three and occasionally four and five nuclei. When we find this nuclear count in one hundred white blood cells is below an average normal we are convinced the resistance of that person is lowered. When repeated similar counts show a constant decrease we know the prognosis is grave. When a constant increase is shown, we know the prognosis is more favorable. I try to make a monthly nuclear count on my patients and derive much satisfaction in prognosticating.

Again it is very common to think and say that a patient has a better chance for recovery when we see an increase in weight, a lessened cough, a lowered temperature, a better color, a better appetite, and a more wholesome optimism. It is easy to show the patient that he is improving and has a splendid chance for recovery when the foregoing things obtain.

There are many other conditions which are often mentioned and upon which a prognosis is based. For instance, unilateral infection compared with a bilateral involvement gives us another reason to assure a patient that he is going to get well. We look upon a case which has a more or less sudden onset with the deepest gravity and consider a case of insidious onset or a type of extreme chronicity with more hopefulness.

Men of good surgical judgment know that a patient with active pulmonary tuberculosis should not be operated upon unless it is absolutely necessary and then under some anesthetic other than ether. This attitude will go far toward lessening regrets. Students of tuberculosis over the country are teaching men who do obstetrics that, as a rule, tuberculous women should not bear children and that in such cases an early abortion is not only justifiable but a right procedure.

Complications nearly always add to the gravity of a case, especially such as tuberculous laryngitis, tuberculous enteritis, or tuberculous otitis media. There is nothing added to our zeal when we find our invaded field is extensive, but when a small lesion is discovered, all things considered, we do not hesitate to say the case is curable. On the other hand we look upon the complications of gout and certain heart lesions with a more favorable prognosis.

Thus far there have been mentioned a few of the many things discussed under the head of prognosis. Your attention might be called to many more things of a similar nature which are usually discussed in medical literature, but I am convinced that there is too much attention paid to science and not enough paid to the so-called common things in tuberculosis.

It is not our intention to discredit science or depreciate the efforts of our research men and other writers in this field of medical literature, for their services have been invaluable in bringing us to our present status in this great work. My purpose is to endeavor to show that prognosis in pulmonary tuberculosis might and should be based upon quite a different line of thought which I believe is neglected and which is very necessary to bring about actual results. I have reference to what physicians say to patients. Up to within the last few years the term "Dark Ages" might be applied to tuberculosis with as much meaning as it was in the early centuries relative to civilization. When a physician is consulted concerning any complaint it is always the patient's desire to know what the diagnosis is. There seems to be no good reason for discriminating against any disease, regardless of what it may be when the physician attempts to say what the disease is. It should be assumed that the patient has intelligence and should have what services he asks for and pays for, regardless of whether he has typhoid, diphtheria, pneumonia, erysipelas, measles, or tuberculosis. Lying to patients who have tuberculosis has cost many a life.

After the diagnosis is made the physician should appoint an hour to go over the whole situation, in a general as well as a detailed manner, with the patient, giving him an insight into what is called "The Tuberculosis Problem" frankly, honestly, and clearly. All questions should be answered and all phases taken up looking toward the enlightenment of the patient, so that he may go away feeling that there is a way out of his trouble without a doubt.

The tuberculosis problem may be put up to the patient after the following fashion: "After conducting my examination which, as you know, included a physical examination of your lungs, a tuberculin test, a family and personal history, a blood test and stereoscopic *x*-ray plates, I find you have tuberculosis. I assume you want to know the truth about the matter or you would not have come to me. Tuberculosis, as you know, is infectious, as are most diseases, and is communicable. There are now two things to do;

*Read at the 20th annual meeting of the Ohio Valley Medical Association at Evansville, Ind., November 11 and 12, 1919.

one is to get well and the other is to make every effort to prevent anyone from becoming infected from you. Your case is absolutely curable and, if you want to get well and are willing to do the things necessary to recover, there is no question about the outcome.

"The cure is much simpler than people know. Formerly it was thought that one must get on a train and go away somewhere where a cure was assured. In addition to this it was thought that the cure lay in a drug store. It was also thought that long walks and vigorous exercises promoted a cure. Up-to-date methods have changed these misdirected notions and substituted new ideas.

"The newest thing in the treatment of your disease is absolute rest. You will find by taking your temperature accurately it will be below normal early in the morning and gradually rise throughout the day until a fever stage is reached some time in the afternoon. We do not feel that fever is good for one, and consequently try to avoid it. In this disease we do not give fever medicine because we have found a better and surer remedy. You know that by walking and exercising you can produce heat in your body. You also know that by resting you can reduce this same heat. This rule applies to sick as well as well people. You can readily see then how the temperature problem is solved. Rest does not only reduce a temperature but lessens the cough which annoys you. Formerly people with your disease took cough medicine. Exercise will also cause one to lose weight. You have already lost weight and are slowly losing more. Rest will increase your weight. It may not seem reasonable to you, but it is a known fact that rest in your condition will improve digestion and a poor appetite.

"Another thing that will go far toward getting you well is fresh air. This is not very new but very important. Some people talk about it but do not get it. Fresh air contains 20 per cent. oxygen, which is very necessary to keep your blood in the very best condition. We have a way of testing blood to see whether or not it is 100 per cent. efficient. In my examination I find your blood measures 95 per cent. in hemoglobin, which is the property of the blood responsible for carrying oxygen from the lung cells to all of the cells of the body, and which keeps the blood to a normal red color. That one thing alone tells me you have not been getting sufficient fresh air. This 95 per cent. can be raised to 100 if you will sleep with your windows open wide and remain in fresh air throughout the day. Each month I will make this test and will find an improvement, provided you follow my instructions. There is another blood test called a nuclear count which I will make each month and which will tell me whether you are improving or not. Some time I will explain this test to you.

"There is quite a little attention paid to food in the treatment of tuberculosis but, for fear I am telling you more than you can remember, I will just mention two things. You must omit any food which you know does not agree with you. Maybe later it will not hurt you. Suppose you do not eat any fried foods, because they are more difficult for you to digest than foods cooked other ways. I mention this because so many people in your condition develop stomach trouble sooner or later. Now, remember, we will discuss the food problem from time to time and later I may have more to tell you.

"Tuberculosis nowadays is considered a sanatorium disease. I mean, that people with this disease should be in a sanatorium, where all rules and regulations looking toward a cure can be carried out. Sanatorium treatment is, or should be, ideal treatment. There you are under orders in regard to rest hours, ventilation, food, hours for reading and many other things that may come up during your cure-taking period. Of course, when I mention sanatorium you have in mind a large building in some far-off State with the word 'Sanatorium' in big gold letters over the front door. Let me give you a new idea about this. This sanatorium, about which I will speak, may be anywhere in the country. It may be your own home. It matters not whether it is a shack, a cottage, a two-story residence or a big stone building. To you it is a sanatorium. Regardless of its structure or locality it is your home until you get well. Your physician will be your superintendent and will tell you what to do, answer your questions, and keep a definite line on your condition at all times. If you are going to stay at home and make your house your sanatorium, I will call and tell you how everything should be arranged. I want you to know that you can take sanatorium treatment at home or away as you choose.

"I can remember when it was almost universally thought that people with tuberculosis must go West. Many people now feel that they must go to North Carolina, while still other thousands feel that Northern New York is the place to go. I find many people have the idea that they cannot get well unless they go Southwest. I want you to know that the exact place for getting well is not agreed upon by people who study the tuberculosis problem. However, there is one thing agreed upon, and that is that there are certain things for the patient to do. We believe that it is not where patients go, but what they do. The proof of this lies in the fact that people get well in every State in the Union. So, instead of worrying about where to go we should make up our minds whether or not we are going to follow advice. If you want to take the rest and fresh-air cure in California, that is your business. If you want to take it in Texas, North Carolina or New York, that is also your business. If you want to take it at home, that depends wholly upon you. There are advantages and disadvantages in staying at home and in going away from home. People who go away from home are not worried by ignorant neighbors constantly telling them that rest in bed will make them weak and hurry them to the cemetery. This, I think, is one of the most detrimental things with which you will have to deal. On the other hand, staying at home keeps one in closer touch with people for whom one cares. This relationship is very necessary to some people, because I do not believe homesick people ever get along very well.

"Now I have told you something of the tuberculosis problem, and hope you appreciate it. You must remember that your disease has been coming on very slowly, and no doubt, for several months. You must expect it to leave slowly. This means you have a long fight, and you must not become discouraged or impatient. You have a will and you must exercise its power. I have seen a great many people recover from tuberculosis by following such advice as I have just given you. I have known many people to die who have not followed this same advice. Take your choice and begin to-day. It is up to you. I shall continue to teach you to rely upon your own efforts for a cure. I may be able to help you myself along the line of scientific treatment, about which we have learned a great deal the last few years. But remember, the fight is yours."

The foregoing is merely a suggestion looking toward proper advice to patients. It is utterly impossible to cover the whole ground in this paper because there is a great deal to say. To start a patient out properly should require at least an hour of the physician's time, discussing things in a simple way such as I have illustrated above. I firmly believe that such advice and such a beginning of the cure-taking period will change the prognosis of many cases that otherwise will end fatally. Too many of our profession want to know how to give tuberculin. Too few know how to talk to a patient. If the interest shown can be reversed, prognosis in pulmonary tuberculosis will be very noticeably and favorably changed.

720 Hume-Mansur Building.

LOCAL ANESTHESIA IN THE RADICAL CURE OF HERNIA.*

By CHARLES T. SOUTHER, M.D., F.A.C.S.

CINCINNATI, OHIO.

FIRST SURGICAL SERVICE CINCINNATI GENERAL HOSPITAL.

THE relative importance of the radical cure of hernia can be appreciated when we realize that six per cent. of the adult male population suffer from some form of hernia. Nearly three million people in the United States are or have been sufferers from hernia in its various forms. A radical surgical operation, properly performed by a skilled surgeon, will cure from 95 to 98 per cent. of those so afflicted. In the hands of less skilled operators a recurrence in 10 per cent. of the cases may be expected.

Preparation of the Patient.—The bowels may or may not be emptied by physic, as pleases the individual operator. A thorough cleansing bath should be given the night before the operation and in the case of unclean patients we may add a 20 minutes warm bichloride bath (75 grs. to the usual tub of water) the night before the operation. The field of operation should be carefully shaved, including the area likely to be covered by adhesive straps to retain dressings. On the table the patient may be prepared as when general anesthesia is to be employed, except that great care should be used not to cause burning from iodine, benzine, or alcohol. None of these agents should be allowed to run down into the groin and to burn the skin over the scrotum or the legs.

Preoperative Medication. — One hour before operation the following preliminary medication may be given: Morphine, gr. ¼; atropine, gr. 1/150. Morphine also tends to counteract any toxic effect of cocaine or novocaine, should a patient have an idiosyncrasy with reference to these drugs. I have not encountered this in any case. Other preparations may act as well, but the above has answered in all cases in my work.

Solutions to Produce Anesthesia.—The following solutions have been used with success for the induction of local anesthesia:

1	Procaine	gr.xii
	Adrenalin chloride, 1-1000	♏xv
	Distilled water, sterile	℥iii
2	Novocaine	gr.xii
	Adrenalin chloride, 1-1000 sol.	♏xv
	Distilled water, sterile	℥iii
3	Cocaine hydrochloride	gr.i
	Adrenalin chloride, 1-1000	♏x
	Saline solution 6/10 per cent	℥i
4	Quinine and urea hydrochloride	gr.vi
	Adrenalin chloride	♏xv
	Distilled water, sterile	℥iii

Operating Table.—Probably the most important single factor, aside from the anesthetic agent, is a comfortable table. It is little short of criminal to expect a patient to remain quiet when on a hard table. Any table will answer provided it is covered by a heavy mattress, four to six inches thick, and wide enough for the arms to rest comfortably. There should be a comfortable pillow for the head and something under the knees. In other words, the patient should be so comfortable that he will not want to move for an hour.

Feeding, Laxatives, Postoperative, Vomiting, Etc.—The patient need not miss any meal, but is less apt to have nausea when only coffee is taken for breakfast on the morning of the operation. Light diet may be continued after operation until the bowels have moved. A cathartic is usually given at end of 72 hours. An enema may be used daily if preferred, or if there is any trouble from gas in the bowel. Vomiting has been present only in cases in which a strangulation existed in which there was handling of intestines, or in which some degree of peritonitis was present. When such conditions exist all food should be omitted.

Incisions should parallel the normal folds of the skin, as nearly as possible, in both inguinal and femoral hernia. The vertical or nearly vertical incisions are followed by more prominent scars.

Suture Material.—Silkworm gut or horse hair for skin. No. 0 catgut, plain, for ligature; No. 2 twenty-day chronic, for suture, in the plastic work proper. Hemostasis must be very complete and perfect.

Operations.—My general preference has been for operations of the Bassini type. The Ferguson operation ranks second, most of the other methods being less worthy or less prominent.

Technique.—After careful preparation of the field, outline a diamond-shaped area with the long

*Paper, with lantern slides showing the technique, read before the Ohio Valley Medical Association at its twentieth annual meeting, in Evansville, Ind., November 11 and 12, 1919.

axis parallel to Poupart's ligament, beginning one inch above and one inch internal to the anterior superior spinous process of the ilium, and ending at the pubic spine; about 5 inches long and 3½ inches wide; 2½ inches above and one inch below Poupart's ligament at its mid portion. Infiltrate all sides of this double triangle with the solution, using about 20 to 25 c.c. Now pass the needle down to the external oblique muscle and, when the point is felt to pass through the apponneurosis of the external oblique, infiltrate the internal oblique, and the cremaster in its portion between the internal and external rings. By this procedure the ilioinguinal and the iliohypogastric will always be bathed in the solution. About 20 c.c. of solution will be ample for all the deep infiltration. As the nerve supply of this region passes through the internal oblique above the internal ring, by infiltrating this area we get perfect anesthesia lower down, where the operative work is carried out. The ten-minute wait before beginning the operation is most important.

Success Depends on this Procedure.—One may then proceed as in general anesthesia, except that great gentleness is essential to perfect success. Sharp dissection with knife or scissors gives the best results. A perfect knowledge of the anatomy is essential to success in this operation.

When the sac is freed and ready to remove it is sometimes necessary to inject a little anesthetic at the neck, where there is pain. This is rarely necessary.

Postoperative Care.—Infection has been no more frequent with local than with general anesthesia. in fact, it has not occurred in any of my cases in which local anesthesia has been employed.

Dressings are changed on the sixth to the eighth day, and skin sutures are removed. The patient remains in bed fourteen days, and should do no heavy work under three months. A light diet is given for four days, regular diet thereafter. The bowels are moved at end of one hundred hours, or earlier, if patient so desires. The patient may assume any position he desires in bed at any time after operation.

I have used local anesthetic in all types of hernia, and at all ages from 14 to 84 years, and in no case have I had to change to general anesthesia. Aged patients are especially good subjects for local anesthesia. The degree of relaxation is even greater, it seems to me, than where ether is used.

Intestinal anastamosis has been accomplished without difficulty.

Conclusions.—1. Local anesthesia in hernia is not the choice of anesthetics for the amateur.

2. With proper knowledge of the regional anatomy, the technique of nerve blocking and infiltration, any of the classical operations for hernia may be completed under local anesthesia.

3. Extreme gentleness in handling the tissues is one of the prime requisites for success in local anesthesia.

4. The nerves are readily identified and need not be cut when proper dissection is made.

5. Tension on sutures should never exceed that necessary for the approximation of the tissues.

6. Every possible detail to promote the comfort of the patient should be utilized.

Suite 43, The Groton Building.

DREAMS.

By H. LAVESON, M.D.,

NEW YORK.

Dreams are very largely the expression of unfulfilled desires. Where, as in children the waking experience and the sleeping differ from each other by very little, the dream, or sleeping experience, readily takes the form of the ungratified desires of the day. But as the mind grows older the dream expression of a desire gets more intricate. Dreams are a part of every one's normal experience, yet they are shown here to be of the same tissue, of the same mental nature, as other phenomena that are undoubtedly morbid.

Let it be granted that a person has undergone a strongly emotional experience—for example, a sudden shock or fright. If the person is highly nervous the shock may result in some degree of dissociation. This may take the form of a loss of memory for certain parts of the experience. By some process the painful experience disappears from conscious memory, but it doesn't cease to exist. It may lie dormant, or it may work subconsciously, and throw up the emotional bubbles that continue, without a known reason to excite the ordinary consciousness (complex).

Dreams can be divided into three classes according to their relation toward the realization of desire. First come those which exhibit a nonrepressed, nonconcealed desire; these are dreams of the infantile type, becoming ever rarer among adults. Second, dreams which express in veiled form some repressed desire; these constitute by far the larger number of our dreams, and they require analysis for their understanding. Third, these dreams where repression exists, but without or with but slight concealment. These dreams are invariably accompanied by a feeling of dread which brings the dream to an end.

Professor Freud has constructed empirical laws out of his masses of material. The dream as it appears to the dreamer he calls the manifest dream ideas. But as these are too absurd to form a coherent reality he gives ground for believing that they represent latent dream ideas. The manifest dream is a mass of symbols representing elements in the latent dream ideas. How the latent dream ideas generate the manifest dream is discovered by psychoanalysis, the translation from the latent to the manifest is the effect of the dream work. The dream work is the very core of the difficulty. It is around this that Professor Freud's greatest subtleties of method are focused. He shows that every dream is linked to something that occurs on the previous day, some recent experience, but the experience emerges in the dream as part of the current panorama of the subjective life, and there is no date to the beginning of the panorama—it may go back to any point in the individual's history, even into the preconscious days of early infancy. The day's experience and the life's experience flow in a single stream, and the images that appear in dreams are but the symbols of all the latent ideas of that experience. How, by displacement of this element or that, compound symbols are formed; how, by the foreshortening of experience and the linking of the past with the present in a single idea, masses of

old memories are clotted into a single point; how, in the freedom of the dream world, where the tension of the waking life is relaxed, where the exacting stimulations of the day are reduced, where the consciousness of duty to be done in the highly organized conditions of social conduct is lowered, where, in a word, the *censor* is drowsy or asleep, where the dream symbols shape themselves into dramatic scenes of endless variety—these it is that Professor Freud's theory endeavors to set forth.

The Dream-Mechanism.—Compression or condensation: It is not at first easy to form an opinion as to the extent of the condensation. The more deeply one goes into analysis, the more deeply one is impressed by it. There will be found no factor in the dream whence the chains of associations do not lead in two or more directions; no scene which has not been pieced together out of two or more impressions and events. The scenes are composite, made out of events that occur at different times and of two or more pictures. The scenes in the dream lead to a whole group of reminiscences, each one of which contributes to the dream content. The stuff of the dream thoughts which has been accumulated for the formation of the dream scene has one or more common factors. The different elements are put one on top of the other; what is common to the composite picture stands out clearly, the opposing details cancel each other. This process of reproduction partly explains the wavering statements, of a peculiar vagueness, in so many elements of the dream. *When there is nothing in common between dream thoughts, the dream work takes the trouble to create a something* in order to make a common presentation feasible in the dream. The simplest way to approximate two dream thoughts which have as yet nothing in common, consists in making such a change in the actual expression of one idea as will meet a slight responsive recasting in the form of the other idea. The process is analogous to that of rhyme, when consonance supplies the desired common factor. Through condensation of the dream certain constituent parts of its contents are explicable.

Displacement.—The dream thoughts which have a claim to the greatest importance are either not present at all in the dream content, or are represented by some remote allusion in some obscure region of the dream. There is no other process which contributes so much to concealment of the dream's meaning, and to make the connection between the dream content and dream ideas, unrecognizable. The psychical intensity, significance, and emotional nature of the thoughts become transposed in sensory vividness. In these dreams not a bit of the dream idea has retained its own psychical value; everything essential in these dream ideas has been replaced by unessentials while every kind of transition between these conditions can be found. The more obscure and intricate a dream is the greater is the part to be ascribed to the impetus of displacement in its formation. The content has a different center of interest from that of the dream ideas.

Before leaving the question of dream displacement let us consider the remarkable process in the formation of dreams in which condensation and displacement work together toward one end. In condensation we have already considered the case where two conceptions in the dream having something in common, some point of contact, are replaced in the dream content by a mixed image, where the distinct germ corresponds to what is common, and the indistinct secondary modifications to what is distinctive. If displacement is added to condensation, there is no formation of a mixed image, but a common mean which bears the same relationship to the individual elements as does the resultant in the parallelogram of forces to its components.

Regression.—The dream thoughts which we learn from the analysis exhibit themselves as a psychical complex of the most complicated superstructure. Their parts stand in the most diverse relationship to each other; they form backgrounds and foregrounds, stipulations, digressions, illustrations, demonstrations, and protestations. It may be said to be almost the rule that one train of thought is followed by its contradictory. No feature known to our reason while awake is absent. If a dream is to grow out of all this, the psychical matter is submitted to a pressure which condenses it extremely to an inner shrinking and displacement, creating at the same time fresh surfaces, to a selective interweaving among the constituents best adapted for the construction of these scenes. Having regard to the origin of this stuff, the term regression can be fairly applied to this process. The dream's means of expression must therefore be regarded as meager in comparison with those of our imagination, though the dream does not renounce all claims to the restitution of logical relation to the dream thoughts. It rather succeeds with tolerable frequency in replacing these by formal characters of its own.

Intelligibility.—These dreams properly made up are the result of an elaboration in every way analogous to the psychical action of our waking life. The dream content is thus secured under the pretense of certain expectations, is perceptually classified by the supposition of its intelligibility, thereby risking its falsification, while in fact the most extraordinary misconceptions arise if the dream can be correlated with nothing familiar. Such dreams are usually short, and, as a general rule, do not seem very noticeable, because everything remarkable or exciting surprise is absent. All signs of a lowered or subdivided psychical activity are wanting. Yet we never raise any objection to characterizing them as dreams, nor do we confound them with the products of our waking life.

Distortion.—These dreams are void of both meaning and intelligibility; they are incoherent, complicated, and meaningless. The overwhelming number of our dreams partake of this character.

Repression.—Viewing the dream content as the representation of a realized desire, and referring its vagueness to the changes made by the censor in the repressed matter, it is no longer difficult to grasp the function of dreams. This conception of repression once fixed together with the distortion of the dream in relation to repressed psychical matter, we are in a position to give a general exposition of the principal results which the analysis of dreams supplies. We learn that the most intelligible and meaningful dreams are unrealized desires; the desires they pictured as realized are

known to consciousness, have been held over from the daytime, and are of absorbing interest. The analysis of obscure and intricate dreams discloses something very similar; the dream scene again pictures as realized some desire which regularly proceeds from the dream ideas, but the picture is unrecognizable, and is cleared up only in the analysis. The desire itself is either one repressed, foreign to consciousness, or it is closely bound up with repressed ideas. The formula for these dreams may be thus stated: They are concealed realizations of repressed desires.

We hold that our psychical apparatus contains two procedures for the construction of thoughts. At the borderland of these two procedures, where the first passes over into the second, a censorship is established which passes only what pleases it, keeping back everything else. That which is rejected by the censorship is, according to our definition, in a state of repression. Under certain conditions, one of which is the sleeping state, the balance of power between the two procedures is so changed that what has been repressed can no longer be kept back. In the sleeping state this may possibly occur through the negligence of the censor; what has been hitherto repressed will now succeed in finding its way to consciousness. But as the censorship is never absent, but merely off guard, certain alterations must be conceded so as to placate it. It is a compromise which becomes conscious in this case—a compromise between what one procedure has in view and the demands of the other.

511 East Eleventh Street.

HUNTINGTON'S CHOREA.*

REPORT OF CASE.

By MORRIS H. FRANTZ, M.D.,

NEW YORK.

INSTRUCTOR OF NEUROPATHOLOGY, NEW YORK POST GRADUATE MEDICAL SCHOOL AND HOSPITAL, ASSISTANT IN NEUROLOGY, NEUROLOGICAL INSTITUTE.

Huntington's chorea is a disease of the nervous system and is said to be hereditary and of marked chronicity. It occurs usually between the ages of 30 and 50. The etiological factors are known to be hereditary. The factors of interest are age, motor disturbance, and mental defect.

Symptoms.—The onset is insidious. There are slight changes in character, and irritability; also jerky choreic movements which cease during sleep. All movements are involved. There is an explosive speech. After several years the patient becomes weak and is confined to his chair. Mental changes often develop independently, perhaps in childhood, such as excitability and eccentricity. These show at the time of development of the choreic movements irascibility, mental instability, and despondency. Emotional deterioration follows.

Diefendorf speaks of a group of Huntington's chorea in which mental symptoms develop and simulate the hebephrenic type of dementia præcox. These suffer from insomnia, malaise and develop ideas of self-reference, anxiety, suspicions, ideas of infidelity, and impulsive tendencies.

Course.—There is often great unrest, mental signs get suddenly worse and patient dies from exhaustion in 5, 10, or 15 years.

Pathology.—There is thickening of the meninges. Others show brain atrophy (loss of cells of the 3d layer). There is a neurogliar increase. Some show arteriosclerosis in which the frontal areas are often involved. In some cases there is rubrothalamico-cortical extension of the cerebellar pathways. Many find changes in the lenticular region as well as in the putamen.

The *prognosis* is bad—the patient dying of exhaustion.

Therapy.—Nihil.

J. C., male, age 34, came to our clinic at the Post Graduate Hospital on Dec. 9, 1918, with the complaint that he has "shaking of the various parts of his body," partial loss of function of the left arm, that he cannot use it very much. Claims this came on after hurting his arm 4½ years ago when it got jammed in between the door and wall. Six months after the accident, he became very shaky, with nervous twitchings of the shoulders, both arms, and legs.

The family history shows the father died at 60, cause unknown; mother living at 62 and well; one brother and one sister living and well. There is no history of any one in the immediate or remote family having had such a condition. The personal history is negative except for the accident described above.

Status præsens: The patient is an adult male, appears his age. Shakes all the time while being examined. Has various grimaces, snorts, smiles at times without any cause. The examination is negative except for the fact that the patient has bad teeth. There is also some irregularity of the heart. There is atrophy of the left forearm with an extensive contracture of the left elbow joint. The patient is well oriented, answers to the point, and so far does not show mental clouding.

The interesting features of this case are the facts that there is no history of any one in the family having had this form of disease and that the patient was apparently without any symptoms of the disease until six months after the accident in which he suffered severe trauma of his left arm. At the present time he works in the local Navy Yard at a skilled vocation in which a certain finesse is required, thereby earning a livelihood. He cooperates exceedingly well and is quite optimistic as to his apparent improvement and as to the progress of his case. He was referred to his dentist for attention to his teeth, and was put on cod liver oil and iron as a tonic, with increasing doses of Fowler's solution.

The question which comes to one's mind is whether or not the injury that the patient suffered was the factor which precipitated the onset of this disease, taking it for granted that there was a neuropathic tendency latent in the patient.

I am indebted to Professor Graeme Hammond for kind permission to report this case.

Hotel Grenoble, Seventh Ave. at 56th Street.

*Presented at a meeting of the Yorkville Medical Society, March 17, 1919.

Typhus in Poland.—The total number of cases of typhus in Poland since January 1, 1919, is given as 170,000 up to about October. The last month available for statistics, September, presented 13,508 cases with 1,192 deaths for the civil population. Among the military for the same month the morbidity was 1,412 cases and 62 death, the combined mortality rate being 8.2 per cent.—*La Presse Médicale.*

Diuretic Action of Ouabaine.—Dufour and Semelaigne presented a case of an alcoholic with cirrhotic ascites, the latter condition reappearing promptly after each tapping. Half a milligram of ouabaine injected into a vein was followed in 24 hours by a profuse diuresis, the quantity rising from 1 to 4 liters for the day. The injections were repeated every second day. At present the ascites has ceased to reform.—*La Presse Médicale.*

THE DIAGNOSIS OF ENCYSTED TUBERCULOUS PLEURISY OF THE APEX.

THE data now in our possession lead to the conclusion that the diagnosis of encysted tuberculous pleurisy of the apex will always be a matter of no little difficulty. Numerous affections may simulate it and therefore should be considered. A pneumonia of the apex may be suspected because of the percussion dullness and absence of the respiratory murmur in the upper lobe, and throughout the area of the fluid collection the voice sounds will have a greater resonance than elsewhere. Now these phenomena are also found in consolidation, while the pain usually complained of at the onset of a pleurisy may be totally absent. A mistake is all the more easy because a certain number of cases of pneumonia of the apex—especially in children—have a single physical sign, namely, dullness, the stethoscopic signs usually being absent. However, the dullness is less distinct in pulmonary consolidation than in fluid collections and does not offer resistance to the exploring finger, and these are the best signs to go by when a radioscopic examination cannot be had. Radioscopy will reveal in pneumonia a shadow extending over the entire apex, but, as Weill and Mouriquaud have recently shown, it is triangular in shape with the base in the axilla and the apex at the hilum, while in encysted pleurisy the lower border of the shadow offers an upward convexity. If doubt remains as to the diagnosis exploratory puncture should be resorted to.

Tuberculous infiltration of the apex, tracheobronchial lymphnodes with congestion of the apex and unilateral pulmonary and lymphnode tuberculosis offer analogous symptoms—dullness and a respiratory souffle with or without râles. In children particularly the research for vocal vibration is often impossible so that the diagnosis may be most difficult. Radioscopy is unquestionably useful because a tuberculous infiltration will give rise to an opacity far less marked and much more diffuse than an encysted fluid collection, while the lower border does not show an upward convex line.

The two other affections which may simulate encysted pleurisy of the apex are hydatid cyst and cancer, both of which give rise to symptoms similar to those of the pleurisy, namely, dullness, decrease of the vesicular murmur, or bronchial souffle. Hydatid cyst usually occupies the middle portion or the base of the apex, while puncture and examination of the fluid withdrawn will settle the diagnosis in doubtful cases. Pulmonary cancer, when extensive, may involve the entire upper lobe, and puncture may not always clear up the differential diagnosis, for in one instance of malignant disease a thick yellow fluid was withdrawn.

Finally, an anterior or posterior mediastinal pleurisy may assume the clinical aspect of encysted pleurisy of the apex. However, one of the anterior mediastinum, whether a purulent or serofibrinous tuberculous pleurisy, is accompanied by more marked pain and dyspnea than that occurring at the apex. The physical signs are found lower down than those at the apex, while the dullness will be more prone to simulate a pericarditis with effusion. On the other hand, the heart will be displaced, but the beats will not be dull so that pericarditis can be eliminated. The radiological examination will reveal an enlargement of the cardiac shadow which is not animated by any beat. Empyema of the posterior mediastinum gives rise to dyspnea, spasm of the glottis, dysphagia, and hoarseness due to paralysis of the left recurrent nerve, all of which are absent in pleurisy of the apex. On the other hand, the physical signs are only to be found in the paravertebral region and radiology reveals a longitudinal opacity filling the clear median space when the thorax is examined obliquely. After all, the best means for arriving at a correct diagnosis of encysted tuberculous pleurisy of the apex is by resort to radiography and exploratory puncture.

ÆQUANIMITAS AND INFLUENZA.

FOR a people so often hard to rouse, we are certainly very easy to throw into a panic. We feed with relish upon the "menaces" served up by the lay press, among the latest of which is influenza, which we seem to have frequently with us. Until we forget the autumn of 1918, the papers will have no difficulty in getting us excited about that baffling disease. We of the profession need not think that we are too imperturbably scientific to be affected by the panic of the multitude. We cannot help it. Our attitude is important; and it is important that we should have an attitude, especially in the early days of an epidemic. Not a few medical men become as panicky as any of their lay brethren and urge their patients not to venture into a world where the pestilence walketh in darkness. Those of us who become thus worried will in all probability report every case that bears any resemblance to "flu"—will take "special precautions," no matter how cumbersome the precautions may be—will accept the disease as dangerous from the start and act accordingly.

Contrasted with those who take the attitude of the alarmist are those who pooh-pooh the whole affair, like the man who, when the flood began, thought the rain would not amount to much. Doctors of

this persuasion will probably let many cases go unreported, rather than add to the startling numbers already published. Health Departments may insist that the disease be reported, but doctors still "use their judgment" in the matter, and means are not at hand to prevent their getting away with it. Many of them do it from motives that are higher than carelessness or indifference, *i.e.* the difficulty of saying just when a "grippy cold" stops and "influenza" begins; or again, reluctance to provide material for the newspapers to start an epidemic of their own.

That cases should be reported as soon as the diagnosis is made is too obvious to require repetition to medical men. The question is: When are we to make a diagnosis? Clearly the lack of a uniform conception of just what influenza is has swelled the totals enormously. Doctors who immediately report a case of fever, malaise, and "cold," will naturally have a higher figure than those who wait a few days to see whether the fever remains high, whether there is persistent leucopenia or marked prostration. Should we diagnose early, on questionable evidence, and arouse the public? Or should we wait till the facts (and often the patients) are all in, and create only warrantable alarm?

For the purposes of proper quarantine (known to be of value against the complications, if not against the disease itself) the early diagnosis, even with a greater percentage of mistakes, has every advantage over the "slow and careful" attitude. In such times alarming the public may be more a virtue than a crime. In fact, the public has a way of disregarding all efforts for its own protection until it gets really scared. The therapeutic measure known to be of the greatest value in this disease is early rest in bed. The first essential to this is acquiescence, a giving in on the part of the patient. And, as nearly all of us are obstinate, fright is essential to acquiescence. Tell a patient that he has the dreaded "flu," and he may obey orders. Tell him that he has a cold or the grippe, and he will go down the street to a movie.

Equanimity is, next to honesty, the greatest virtue a medical man can have. It is in greatest demand in time of epidèmics. But, if carried to the extent of harmful procrastination and optimism, it smacks too much of lethargy to be virtuous. A public worried about disease is far more likely to be healthy than a public indifferent to disease, Mother Eddy to the contrary notwithstanding.

DYSPNEA AND EARLY DEATH IN ARTERIOSCLEROSIS.

In subjects in advanced years presenting arteriosclerosis nocturnal paroxysms of dyspnea, related manifestly to the patient's diet, are common. The attacks take place at a regular time, from two to four hours after the evening meal, at a time when the stomach is still filled with food. This dyspnea and the insomnia which often goes with it are about the only functional disturbances met with in these patients who have aortic lesions and a high blood-pressure. They come to hospital with the most varied diagnoses on the part of the attending practitioner. The antecedents do not reveal any major infectious disease in their past, but an intoxication, a chronic infection, and often overwork will be noted. Although these subjects may at a given time present anginal attacks and pulmonary edema, and although they have an emphysema, and the pain and respiratory distress may be increased from this fact, nevertheless the paroxysms of dyspnea are directly dependent upon the diet. They are produced by the food toxins and rapidly give way to a milk diet which has the advantage of being only slightly toxic and facilitates the elimination of the poisons, while at the same time the volume of food is reduced.

The paroyxsms of dyspnea may terminate favorably, and the patient progressively returns to his normal state, but he will always be menaced with the return of the accidents the moment he gives up the diet. If this is exactly followed, extremely long remissions will be noted. The prognosis of these paroxysms of dyspnea is all the more serious, the further the arteriosclerosis is advanced. They may result in rapid death, which also is dependent on the intoxication. In order to forestall these accidents, or at least to diminish their frequency, it is absolutely necessary to subject the patient when he is convalescent to a special diet and follow the case closely thereafter. By so doing the physician may keep the patient in a fair state of comfort for some time.

PROGRESS IN OUR KNOWLEDGE OF VARIOLA.

FEW medical men realize the advances recently made in our knowledge of smallpox, largely because we have had little experience with the disease in recent years. An article by Söbernheim in the *Correspondenz Blatt für Schweizer Aerzte* for December 4, 1919, xlix, 49, calls attention to the possibilities of diagnosis by laboratory methods. The various serological and microscopical tests have been shown to be worthless, but Paul's inoculation test on the rabbit's cornea has more than made good, although negative results are inconclusive. In a typical behavior the presence or absence of Guarnieri's corpuscles, which alone would be of no practical value, may be invoked. The preliminary work in Paul's test is simple, for it is only necessary to send suspicious pus, which has been smeared on a cover glass and dried, to the nearest laboratory. The cornea of the rabbit is scarified and the pus rubbed in, whereupon in 36 to 48 hours characteristic macroscopical appearances known technically as epitheliosis may be studied by the lens. The eye is afterwards enucleated and studied at leisure. It is of extreme interest to note that only smallpox virus and vaccine matter can cause this reaction, a proof apparently of identity of virus. We have also recently learned that in smallpox the greatest danger from contagion may be through the secretions of the nose and nasopharynx, which can transmit the disease at an early period. Paul's test has also shown that the sputum is infectious, and these discoveries make it easy

to understand how the disease may be air-borne within a short radius. Finally Paul's test has given us the comforting assurance that in all probability there is no such person as a healthy smallpox carrier. The theory of the contagion of the pustules late in the disease is not attacked, for there is no reason whatever to doubt this fact, crusts having been used for centuries for inoculation of variola.

Influenza or Epidemic Sepsis.

Saxorrafos of Athens asks this by no means novel query in *Le Bulletin Médical* for January 3, 1920, xxiv, 1. The author was reminded in these cases of fulminating influenzal sepsis of the same phenomenon as witnessed in scarlatina and mixed infection of diphtheria—in other words, of streptococcemia *per se*. The fact of renal participation was as potent as any in suggesting this analogy, nephritis being a common lesion in sepsis but rare in ordinary influenza. A syndrome common in his experience was as follows: initial headache, coryza, angina, and fever, all mild; coated tongue, anorexia, nausea; then after 12 to 14 hours sudden rise of temperature to 104° or so, with a very irritable cough like pertussis, and dyspnea; this development seemed to mean invasion of the lobules of the lung. The patient, thus far in satisfactory general condition, becomes restless and the urine is found to be loaded with albumin and to have a sediment of casts and renal epithelia. Oliguria may be added. Headache becomes intensified and the patient becomes acutely septic. Upon this background asphyxia develops and death follows from acute edema of the lungs. The sputum contains the strepto- and pneumococcus. By legitimate expansion of this syndrome most of the phenomena of the late pandemic are covered and the various clinical types correlated into a picture of acute sepsis. Whether or not typical bronchopneumonia was present need make no essential difference. In arguing for a dualism between the late pandemic and that of 1890 the author stresses the renal complications, but in the older episode there was a wake of albuminuria which made it difficult for insurance companies to do business for a couple of years; so much was this the case that the medical director of one of the large old line companies felt obliged to visit personally some of the leading provincial examiners to arrange a *modus vivendi* to meet these numerous postponements for post-grippal affections.

Vitamines in the Urine.

It has been shown in the case of pigeons that they can thrive on a diet of whole rice, but when this article is changed to polished rice there appears after an incubation of 15 or 20 days fatal polyneuritis or artificial beriberi. Gaglio, who represents in part his colleague Roseo, who carried out the experiments, was able to show that by giving a few cubic centimeters of human urine daily one can prevent this catastrophe, whence it appears that the urine of healthy human beings contains vitamines (*Il Policlinico*, November 23, 1919, xxvi, 47). Even a few hours after 3 or 4 c.c. of urine previously concentrated on a water bath have been administered, the animal revives and makes abortive attempts to walk and fly. Complete recovery follows the use of the remedy two or three times daily over a short period. If polished rice and urine are given together the animal does well for several days, but later develops a mild type of polyneuritis. The experiment appears to show that the surplus vitamines formed daily from the food are eliminated by the kidney. There are also substances which may be derived artificially from pyridine and pyrimidine and their congeners, and from xanthin derivatives, which if not entitled to be called vitamines at least behave in similar fashion in connection with artificial polyneuritis of birds.

News of the Week.

Osler Memorial Meeting.—A meeting in memoriam of Sir William Osler, M.D., will be held at the New York Academy of Medicine on Saturday evening, February 21, at 8:30 o'clock. Addresses will be made by Drs. Welch of Baltimore, Craig of Philadelphia, Cushing of Boston, and Shepherd of Montreal.

Physicians in New York, New Jersey and Connecticut.—The Medical Directory of New York, New Jersey, and Connecticut for 1919, compiled under the direction of the Medical Society of the State of New York, has recently appeared. It contains the names of 14,446 physicians in New York State (8,100 of whom are in New York City), 2,767 in New Jersey, and 1,421 in Connecticut.

Mortality Statistics for 1918. —The Census Bureau's annual compilation of mortality statistics for the death registration area in continental United States shows 1,471,367 deaths as having occurred in 1918, representing a rate of 18.0 per 1,000 population. This rate, the highest on record in the Census Bureau, is due to the epidemic of influenza. Of the total deaths, 477,467, or over 32 per cent., were due to influenza and pneumonia (all forms), 380,996 having occurred during the last four months of the year, during the influenza pandemic. The next most important causes of death were organic diseases of the heart, tuberculosis (all forms), acute nephritis and Bright's disease, and cancer, which together were responsible for 391,391 deaths, or nearly 27 per cent. of the total number. Next in order of frequency were apoplexy, diarrhea and enteritis, arterial diseases (atheroma, aneurysm, etc.), whooping cough, diabetes, bronchitis, diphtheria, typhoid fever, and measles.

Red Cross Aids in Thirty-nine Disasters in 1919. —According to recent announcement, the Red Cross spent approximately $421,000 during the past year, aiding victims of thirty-nine of the most serious disasters in the United States. These disasters resulted in 650 deaths, injury to 1,800 persons, and property losses of $25,000,000 to about 50,000 persons.

Impertinent Advice to Practitioners of Medicine.—During the recent regional conference of the W. C. T. U., with delegates from fifteen States, resolutions were introduced protesting against the use of whiskey, the "discredited drug," in influenza. Also, William H. Anderson, of the Anti-Saloon League, in a recent address, had the impudence to impeach the honesty of physicians who

prescribe whiskey for influenza, holding that "the doctor who defends alcoholic liquor as medicine argues from his appetite or his prejudice instead of from his judgment or any scientific knowledge."

Strike Among Insane Patients. — According to press reports, the patients at the territorial hospital for the insane at Honolulu, who have been working in the tailor shop, making clothes for themselves and other patients, have gone on strike, refusing to work unless paid for their labor.

Dr. Seymour Oppenheimer of New York City has been appointed by Gov. Smith a trustee of the State Institute for the Study of Malignant Diseases.

Charged with Violating the Harrison Law.—Dr. Ernest S. Bishop of New York City was arraigned before Federal Judge Hough on February 10, and held in $5,000 bail, charged with violating the Harrison Drug Law. The indictment charges the defendant with prescribing morphine, heroine, and cocaine in excessive amounts and contrary to the legitimate practice of medicine, to habitual users of narcotic drugs. When arraigned the defendant pleaded "not guilty," and was released on bail pending trail. Of course, no one who knows Dr. Bishop can for a moment believe that his offending was other than technical, and the trial when it comes off will without doubt make this clear to the dullest or most prejudiced mind. The charge is, however, a very serious one, and Dr. Bishop's friends will sympathize with him in his trouble and wish for him a speedy trial and triumphant acquittal.

Junior Red Cross Activities.—During the war the school children of America, through the Junior Red Cross, produced 15,722,078 relief articles to an aggregate value of $10,152,461.

Austrian Birth and Death Rates.—During the past year, according to reports from Vienna, there were 50,000 deaths in Austria, while there were only 18,000 births. In 1913 there were 36,000 births and 33,000 deaths.

American Red Cross Nurses in Europe.—Miss Alice Fitzgerald, recently appointed chief nurse to the League of Red Cross Societies, gave the number of nurses in Europe on November 1, 1919, as follows: France, 30; Italy, 7; Palestine, 7; Near East, 60; Balkans, 61; Russia proper, 2; Siberia, 139 to 160; Poland, 10; Greece and Serbia, 6; Persia, 1. From now on only very few specially trained nurses with unusually high qualifications will be sent abroad.

Cholera at Brest-Litovsk.—In consequence of the impure water supply and the large number of prison camps situated at Brest-Litovsk, this has long been recognized as one of the most unsanitary localities in central Europe. Cholera has broken out there, and Brest is under quarantine, as is also Kowel, a railroad center on one of the main traffic lines to Brest. The Polish Ministry of Health immediately requested the cooperation of the American Red Cross in the institution of precautionary measures. Within a few hours laboratory material and apparatus for cholera diagnosis were assembled from the American warehouses, and a thoroughly equipped vaccine coach was on its way, behind a special locomotive, to the scene of the threatened epidemic. American pathological experts made supplies of vaccine and conducted analyses in their railway-car laboratory unit, pending the arrival of Polish bacteriologists.

Natality Division of Ministry of Health of France.—President Poincaré issued a decree on January 27 creating a Council of Natality of the Ministry of Health, the duty of which is to deal with the need of France for more children. The decree provides that the council shall consist of thirty members, and must meet once a month. Among the duties imposed upon this body are "to examine all measures which may combat depopulation, increase the birth rate, develop puericulture, and protect and honor large families." As soon as possible it is to recommend laws which will put their findings into effect. In the meanwhile it is gratifying to learn from the press despatches that Paris maternity hospitals are filled to overflowing, and are asking the government for more funds with which to take care of the hundreds of cases for which they now have no room.

War Prisoners in Siberia Succumb to Smallpox and Typhus.—According to dispatches to the International Red Cross headquarters at Geneva nearly 375,000 of the 500,000 Austro-Hungarian prisoners of war taken by Russians have died in Siberia from smallpox and typhus. The rest are kept alive only by the efficient work of Japanese, American, and English physicians assigned to towns along the Trans-Siberian Railway.

Medical Fraternity Meets.—The Phi Delta Epsilon Fraternity held its sixteenth annual session in Philadelphia January 2 and 3. Officers for the ensuing year were elected.

The Medical Section of the American Life Convention will hold its tenth annual meeting at French Lick, Indiana, March 10-12.

League of Red Cross Societies.—The first general council of the League of Red Cross Societies will meet at Geneva, March 2. Delegates from each national society have been invited. It is proposed at this meeting to map out a program for the advancement of health, prevention of disease, and alleviation of distress throughout the world.

Spotted Fever in Galicia.—According to advices from Switzerland January 22, there were more than 100,000 cases of spotted fever in Eastern Galicia and more than 10,000 deaths have resulted.

Medical Society Elections.—The RHODE ISLAND HOMEOPATHIC SOCIETY, at its seventieth annual meeting, held January 9 at Providence, re-elected the officers who had served during the past year. These are: *President*, Dr. William M. Muncy; *Vice-President*, Dr. James H. Prior; *Secretary*, Dr. Martha Boyce Bates; *Treasurer*, Dr. Marion Albro Gleason.

THE WASHINGTON COUNTY (R. I.) MEDICAL SOCIETY, at its annual meeting, held at Westerly January 8, elected the following officers for the ensuing year: *President*, Dr. P. J. Manning, Wickford; *First Vice-President*, Dr. Henry L. Johnson, Westerly; *Second Vice-President*, Dr. William Veal, Stonington; *Secretary-Treasurer*, Dr. W. A. Hillard, Westerly; *Auditor*, Dr. Samuel C. Webster, Westerly.

THE NASHVILLE (TENN.) ACADEMY OF MEDICINE

and the DAVIDSON COUNTY MEDICAL SOCIETY, at a joint meeting held in Nashville January 6, elected the following officers for the two societies for the coming year: *President*, Dr. W. C. Dixon; *Vice-President*, Dr. S. M. Bloomstein; *Secretary* (re-elected), Dr. Jack Witherspoon.

THE COLUMBIA (S. C.) MEDICAL SOCIETY, at a meeting held January 12, elected the following officers for the ensuing year: *President*, Dr. George H. Bunch; *Vice-President*, Dr. LaBruce Ward; *Secretary-Treasurer*, Dr. Floyd D. Rodgers.

THE KNOX COUNTY (ME.) MEDICAL SOCIETY elected the following officers for the ensuing year: *President*, Dr. Walter M. Spear; *Vice-President*, Dr. J. G. Hutchins; *Secretary-Treasurer*, Dr. D. North.

THE SPARTANBURG (S. C.) MEDICAL SOCIETY, at its annual meeting held December 20, elected the following officers to serve during the coming year: *President*, Dr. D. L. Smith; *Vice-President*, Dr. W. E. Lyles; *Secretary*, Dr. J. E. Edwards; *Treasurer*, Dr. Oscar B. Wilson.

THE SOCIETY OF AMERICAN BACTERIOLOGISTS, at a meeting held December 31, at the Massachusetts Institute of Technology in Cambridge elected the following officers for the coming year: *President*, Dr. Charles Krumwiede of the research laboratory of the New York City Health Board, succeeding Professor S. C. Prescott of Massachusetts Institute of Technology; *Vice-President*, F. C. Harrison, President of MacDonald College, Montreal; *Secretary-Treasurer*, Dr. A. Parker Hitchens (re-elected). Dr. L. A. Rogers of the Bureau of Animal Industry, Washington, D. C., was made delegate to the American Association for the Advancement of Science.

THE YORK COUNTY (MAINE) MEDICAL SOCIETY, at its ninety-ninth quarterly meeting held January 7, elected the following officers for the ensuing year: *President*, Dr. F. D. Smith, York Village; *Vice-President*, Dr. Paul S. Hill, Saco; *Secretary*, Dr. A. L. Jones, Old Orchard; *Treasurer*, Dr. Carl G. Dennett, Saco.

THE MEDICAL AND SURGICAL ASSOCIATION OF THE SOUTHWEST, at the close of its fifth annual session, held at El Paso, Texas, elected the following officers for the ensuing year: *President*, Dr. Warner Watkins, Phoenix, Ariz.; *First Vice-President*, Dr. James Vance, El Paso, Texas; *Second Vice-President*, Dr. M. K. Wilder, Albuquerque, N. M.; *Secretary-Treasurer*, Dr. J. R. Van Atta, Albuquerque, N. M. The next annual meeting will be held at El Paso.

THE CUMBERLAND COUNTY (ME.) MEDICAL SOCIETY, at its annual meeting held in December elected the following officers: *President*, Dr. Francis J. Welch; *Vice-President*, Dr. Daniel Driscoll; *Secretary-Treasurer*, Dr. E. E. Holt, Jr.

Obituary Notes.—Dr. THOMAS F. CONNEEN of Portland, Me., died suddenly January 21 from cerebral hemorrhage, in his forty-fifth year. He was graduated from the Medical School of Maine in 1901. He was a member of the American Medical Association, Practitioners' Club, and other organizations.

Dr. LEWIS WHITE CALLAN of New York City died of pneumonia January 21, at the age of 42. He was graduated from the Medical Department of the University of Pennsylvania in 1901, and specialized in ophthalmology. He was connected with the New York Eye and Ear Infirmary, and was ophthalmologist to the Lying-In Hospital. He was a member of the American Ophthalmological Society and the American Medical Association.

Dr. JOHN D. KELLY, New Haven, Conn., died suddenly from cardiac disease January 11, at the age of 73. He was graduated from New York University Medical College in 1880.

Dr. JOHN AUSTIN KANE of Brooklyn, N. Y., died of pneumonia January 23, at the age of 41. He was graduated from Harvard Medical School in 1902. He was a member of the American Medical Association.

Dr. FRANK B. FULLER of Pawtucket, R. I., died suddenly from cardiac disease January 23, in his sixty-seventh year. He was graduated from the Medical School of Harvard University in 1878. Dr. Fuller was a member of the American Medical Association and of various local organizations.

Dr. PATRICK J. HUGHES of Lawrence, Mass., died January 26, at the age of 42. He was graduated from University and Bellevue Hospital Medical College in 1902.

Dr. JULIUS S. CLARK of Melrose, Mass., died January 27, at the age of 81. He was graduated from the Georgetown University School of Medicine, Washington, D. C., in 1869. Dr. Clark was a veteran of the Civil War, and a member of the Massachusetts Medical Society, and other organizations.

Dr. M. G. OVERLOCK of Worcester, Mass., died January 30, at the age of 54. He was graduated from Baltimore Medical College in 1896. Dr. Overlock made a special study of tuberculosis, and was instrumental in securing legislation requiring the maintenance of tuberculosis hospitals in cities and towns of Massachusetts.

Dr. GEORGE VICTOR GENZMER, Lieutenant M. C., U. S. N. R. F., of Albany, N. Y., died of pneumonia at Verona, N. J., on January 30, at the age of 29. He was graduated from Albany Medical College in 1913.

Obituary.

ELMER ERNEST SOUTHARD, M.D.,

CAMBRIDGE, MASS.

Dr. ELMER ERNEST SOUTHARD of Cambridge, Mass., Assistant Professor of Psychology at Harvard University and Bullard Professor of Neuropathology at Harvard Medical School, died of pneumonia at the Prince George Hotel, New York City, February 9. He had come to New York February 1 to deliver two lectures, and had spoken before the New York Neurological Society February 3, and the Association of Mental Hygiene on the fourth. He became ill the following night, succumbing to the disease on the third day of his illness.

Dr. Southard was born in Boston, July 28, 1876. He was graduated from Harvard University in 1897, and from Harvard Medical School in 1901, receiving the degree of Master of Arts from the university in 1902. He served as interne and assistant in pathology in the Boston City Hospital, and later as visiting pathologist in the same institution. In 1904 he became instructor in neuropathology in Harvard Medical School, and was

made Bullard professor in the same department in 1909. From 1906 to 1909 he was assistant physician and pathologist to the Danvers State Hospital for the Insane, and from 1909 to the time of his death he was pathologist to the Massachusetts Commission on Mental Diseases. Since 1912 he had been a director of the Boston Psychopathic Hospital, and at the time of his death he was a director of the Massachusetts Psychiatric Institution. In 1917 he received the honorary degree of Doctor of Science from George Washington University.

Dr. Southard's literary activities were varied and extensive. He was assistant editor of *The Journal of Nervous and Mental Diseases*, *The Psychiatric Bulletin*, and *The Journal of Clinical and Laboratory Medicine*. He was the co-author with Dr. H. V. Solomon of "Neurosyphilis," and of the "Weekly Research Papers," with Dr. H. E. Fernold. His "Shell-Shock and Other Neuropsychiatric Problems" appeared quite recently. He contributed to many periodicals.

During the war Dr. Southard was major in the Chemical Warfare Service, at the same time serving as chairman of the Committee on Psychiatry and Neurology of the National Research Council.

He was a director of the Bedford Hills Laboratory Bureau of Social Hygiene, a member of the American Academy of Arts and Sciences, the Association of American Physicians, the Massachusetts Medical Society, the American Neurological Association, the American Association of Pathologists, the Society of Experimental Biology, the American Psychopathological Association, and other local and national organizations.

Correspondence.

SOME TUBERCULOSIS QUESTIONS.

To the Editor of the Medical Record:

Sir:—For the sake of eliciting discussion, and to stimulate thought and study of a very important subject, allow me to submit the subjoined tenative answers to the unanswered questions in Dr. Stephen J. Maher's illuminating article, printed in your issue of January 10, just received. He states that the war has emphasized nothing concerning the cause or cure of tuberculosis: may not this be due to the fact that causes are myriad, and cures rare? Does tuberculosis always begin in childhood? Yes, in nearly every human being; the weak develop it, the vitally resistant do not. Can one contract the disease in adult life? No, adults do not contract, they develop it. Why more tuberculous men than women? Because of outdoor work, alcohol, and tobacco; women as women have far greater resistance to disease than men have. Why does sunlight therapy help bone and gland tuberculosis, and fail in the pulmonary form? Because bone and gland tissues can renew and repair themselves, while lung tissue, once destroyed, is never renewed. This answers also the question next in order in Dr. Maher's list, on this point.

Are all tubercle bacilli born of other tubercle bacilli. They are. What is the relation to tubercle bacilli of other acid-fast bacilli? None of importance to this inquiry, so far as we know at present. How dangerous to adult human beings is the milk of tuberculous cattle? Sufficiently, if taken as a habit, to aid in developing disease from a latent condition of early infection, especially in congenitally weak constitutions. Are tuberculous cattle always infected by other tuberculous cattle? No doubt they are so infected, though unfavorable conditions may contribute to prepare the soil for the seed. Non-tuberculous cattle would be apt to become ill, if subjected for any length of time to the unsanitary conditions specified in Dr. Maher's next question; whether they would develop tuberculosis or not would depend upon the possibility of previous infection, in each case, except that one developed case would endanger the others. As for the vaccinating power of avian, bovine, or other acid-fast or nearly acid-fast bacilli in human tuberculosis, the answer is they would have none of importance, so far as we now know.

The relation between tuberculosis and measles, or exanthemata in general, is this, that all these diseases, some to a less degree than others, tend in their results to contribute to the development of tuberculosis at a later or earlier period, if the subject be weak constitutionally. Especially measles, whooping-cough, gonorrhea, and syphilis, pave the way directly for the future manifestation of a latent infection, in a tuberculous diathesis.

The explanation of immunity, in large measure, is the absence of these contributing conditions, and the fact that in many cases an early infection acts, or appears to act, quite like a vaccination. Grinders' and miners' tuberculosis is referable first to an early infection, rooted by a congenitally subnormal resistance, and later developed through constant irritation of the respiratory organs by inbreathed dust. The same is true of workers in cotten, woollen, and silk mills, to which may be added the effects of long confinement in ill-ventilated or damp places of work, with monotonous and wearing toil, too many hours a week.

It is of interest to remark here that workers in dry and dusty materials, such as metals, cloth, paper, wood, grains, and articles made of the same, appear to be much more liable to develop tuberculosis than workers in oils, fruits, vegetables, meats, fish, and moist materials in general.

In conclusion, patient inquiry into the probable genesis of tuberculosis, among thousands of cases, has convinced one student that the inherited weakness, whatever be its cause or causes, and their name is legion, is by far the largest factor in the development of tuberculosis. Poor nutrition in childhood, carelessness of one's health in adolescence, and disregard of ordinary rules of hygiene in adult years, together with insanitary environment at any time of life, combine to prevent the individual from throwing off the latent infection, or carrying it successfully to the grave.

OUR LONDON LETTER.

(From Our Own Correspondent.)

London, Jan. 30, 1920.

National Compulsory Insurance and the Medical Profession in Great Britain.—On July 15, 1912,

the Act for National and Compulsory Sick Insurance came into operation. The entire industrial population of Great Britain was brought within the scope of this scheme, whatever the earnings of individual workers, together with all employed persons, whatever the value of their occupation, whose earnings did not exceed £160 ($800) a year. There were certain exceptions. Under the scheme the necessary funds are raised by contributions from the employer and the employed, and by direct grant from the state. An Insurance Fund of £20,000,000 ($100,000,000) was formed and nearly 14,000,000 persons were brought into insurance in the first week in October, 1912, the total number of societies involved in the payment of sickness benefit and maternity benefit to their members, operating in England, which had applied for approval was 2,391, of which 2,161 had been approved. According to a return for the quarter ending October 13, 1912, the total number of insured persons in England was given as 10,862,021. Of this number 10,325,000, of whom about 7,000,000 were men and the remainder women, were insured in friendly societies, trade unions, and employers' societies and industrial companies, amounting to 95 per cent. of the whole. The remainder of the injured resided in Scotland and Wales. On the question of the medical treatment provided under the Act, one point even so long ago as April, 1913, stood out clearly and that was that the then arrangements could not by any means be regarded as final. Controversies galore took place between the medical men and the commissioners. On April 14, 1913, it was stated that there were over 18,000 doctors on the panel, or between 80 and 90 per cent. of the total number of medical practitioners engaged in industrial practice. At that time it was found that the "free choice" of doctors which had been one of the great attractions of the Act when explained on the political platform, had been considerably watered down in practice, and even a change from one practitioner to another, when both were on the panel, could be effected only with great difficulty by the insured person; and as might be expected there has been an official fixity about all the arrangements which has led to a good deal of minor hardship and friction. One point has been made abundantly clear, and that is that many insured persons prefer to employ doctors of their own choice at their own expense rather than be attended by those on the panel and so enter into the class of panel patients.

The Act provided that for each patient on one panel the doctor should receive a sum of nine shillings per annum, about $2.25. A mileage fund of £300,000 ($1,500,000) was also founded for England and Wales to compensate for the greater work and outlay of the rural practitioners. Some other benefits accrued to panel medical men, but it would take a volume to explain fully all the ins and outs of the Act, with respect to medical attendance. It will suffice therefore to say that speaking broadly the panel practitioner received for each patient the sum of $2.25 a year, and that while this may appear a somewhat ludicrously small amount, it was at least double the sum that he received yearly from contract practice with the approved societies. So far as the panel doctors themselves were concerned, there can be no doubt that up to the time of the outbreak of war, the Act had been on the whole markedly beneficial to their incomes, especially to the incomes of those who worked in industrial districts. It is doubtful if the quality of the treatment given to the insured was always what it should have been. Perhaps, it not infrequently savored somewhat too much of the rough and ready variety. It has been stated that some doctors had more patients by far on their lists than they could possibly attend to. This is doubtless true. For instance, after the Act had been in working order for a year and a half or so, figures showed that out of 300 panel practitioners in Manchester, one had an income of £1,980 ($9,900), thirteen incomes between £1,000 ($5,000) and £2,000 ($10,000), eleven incomes between £800 ($4,000) and £1,000 ($5,000), thirty-two incomes between £500 ($2,500) and £800 ($4,000), and forty-seven incomes between £300 ($1,500) and £500 ($2,500). A similar state of affairs prevailed in Leeds and no doubt in all industrial centers.

The British National Insurance Act in its relation to the medical profession has not altogether fulfilled the gloomy predictions which were so freely made concerning it, and generally speaking it might perhaps appear that medical practice in Great Britain under the Act has not proved so irksome or so laborious as had been expected. But the working of the Act has been only partially satisfactory so far as the administration of medical benefit goes. A certain number of medical men have benefited pecuniarily by the new legislation. It seems to have but continued or intensified the old abuses of contract practice. In some parts of the country it works in a sufficiently satisfactory manner, while in other parts it has at least effected no improvement upon the older methods. It has certainly greatly emphasized and aggravated the hospital question by increasing the demand for that kind of treatment which the hospital alone can supply. With regard to the organization and administration of sanatorium benefit, the Insurance Act has been rather a drawback than an aid. As a rule, institutional treatment is available for tuberculosis only, provided that the sufferers are both curable and insured. There is no treatment for incurable cases, even if insured.

At the time the war broke out the defects of the Insurance Act may be summarized briefly as follows: The objectionable features of club, that is contract, practice have reasserted themselves. The greater part of insurance work is not evenly distributed or anything like evenly distributed, but tends to fall into the hands of a relatively few popular practitioners with the evil result for their patients that they may and do undertake more than they can adequately manage. Perhaps a certain amount of cleavage has arisen between panel and non-panel doctors, tending towards the creation of class, that is rich men's and poor men's doctors. It has led probably to some malingering, as sickness is found to be suspiciously high in many places. Lastly, the pecuniary strain on the hospitals has been intensified and over-pressure has occurred amongst medical men.

In a broad sense this was the situation at the outbreak of war. Of course, the war caused so great

an upheaval in every way that panel medical service was to a great extent disorganized. Since the armistice the cost of living has advanced by leaps and bounds, and although the proud practitioners have resumed to some extent the even tenor of their ways, they have naturally discovered that they are unable to live properly on the same incomes as before the war. Consequently, they have asked for an increase of yearly capitation fee from nine shillings ($2.25) or thereabouts to thirteen shillings and sixpence ($3.37). As the result of a conference between Dr. Addison, Minister of Health, and the Insurance Acts Committee of the British Medical Association, a provisional arrangement has been arrived at on the subject of the remuneration of insurance medical practitioners. Dr. Addison informed the deputation that waited upon him that the Government was prepared to seek the authority of Parliament for the provision of funds necessary to pay insurance doctors an increased yearly capitation fee of eleven shillings ($2.75). The doctors' representatives stated that as their conference had resolved on thirteen shillings and sixpence ($3.37), they would feel bound to recommend their constituents not to accept the eleven shillings ($2.75) capitation fee, but they were empowered to ask for arbitration, which they did. Dr. Addison acceded to this request. There is to be an independent board of arbitrators to fix the fee, and its award will apply as from April 1, 1920. Meanwhile for the first quarter of this year the rate is eleven shillings ($2.75).

A few days ago Dr. Addison received at the Ministry of Health, a representative deputation from the British Federation of Medical and Allied Societies in regard to the National Insurance Act. Dr. Arthur Latham said they were there to emphasize the fact that National Health Insurance did not permit the insured person to receive all that the science of medicine had to give, and that under the regulations the panel practitioner was not able to do the effective work he was willing and anxious to do. They had before them the lessons of five years' experience during the war of the most gigantic experiments in health services that the world had ever seen. The public and medical conscience had been deeply stirred in health matters and the public and profession had learned what medicine had to give to the community. The insured public asked for bread and were given a stone; they asked for health, and were given regulations which seemed to be chiefly designed to catch the erring doctor in some fault. The tendency of the regulations was to impair the efficiency of health services. There must be regulations, but if they were not to hamper efficiency, they must be elastic and interpreted in the interests of the health services. The deputation suggested it would be well to institute a public inquiry into the working of the medical provisions of the Insurance Act. In the course of his reply Dr. Addison said that if he thought any advantage could be gained by a public inquiry, he would not hesitate to recommend it. They wanted to get a better coordinated service which would be acceptable to the medical profession and more useful to the public. It was not possible quickly to evolve a health system which would be sound and efficient. The complexities of the problem of the health service were immense and it involved the biggest administrative rearrangement in the public services of the country that had confronted any department in this generation.

The Insurance Act of Great Britain as it concerns the medical profession, judged by the two years or more test of experience before the war, is on the whole satisfactory neither to the panel practitioner nor to the insured person. By it the abuses of contract practice have reasserted themselves and on account of the flocking of patients to certain men, these men have not the time to do their work properly, while other panel men are left out in the cold with little to do. It appears that at the present time as much objection is raised to the numerous and tiresome regulations as to the inadequate pay. The point has been raised on several occasions recently that the Insurance Act is obviously copied from Germany, and in its essence and principle is directly opposed to the genius of the English speaking race for individuality and initiative. According to accounts before the war, the National Insurance Act of Germany as regards both medical men and patients, had not been a conspicuous success. If in disciplined Germany with its bureaucratic ideals, it had not been distinctly successful, how could the system be expected to thrive among independent freedom-loving Britishers? Moreover, it is thought by some that the Act may be employed as a lever by the almost omnipotent approved societies to take away the independence of the medical man. The medical profession is practically impotent politically. It may be the thin edge of the wedge to open the way to a State Medical Service, and the day may be coming in Great Britain more rapidly than is imagined when the medical man will be the servant of the State and his duty will be rather to prevent than treat disease. In the meanwhile it may be said that National Insurance from the doctor's and patient's standpoint is susceptible of much improvement, and it is hoped that the Government and medical profession will pursue a policy of give and take, with the main object of caring for the health of the community in the best possible way.

Obituary.—The death has just taken place at the age of 60 years of Dr. Cecil R. C. Lyster, who has fallen a victim to this self-sacrificing devotion to the work of *x*-ray research. He received his medical education at Charing Cross Hospital, where he afterwards acted as assistant medical officer and obstetric officer. For a time he was medical superintendant of Bolingbroke Hospital and in 1902 went to the Middlesex Hospital to take charge of the electrotherapeutic department. He was a pioneer in *x*-ray investigation, particularly in relation to the treatment of cancer, and latterly carried out much valuable research on the use of radium as a remedial agent. In the earlier periods of his work little was known concerning the properties of *x*-rays and the means for preventing their harmful action on the operator, and Dr. Lyster sustained serious injuries. He might have recovered, perhaps, had he ceased to experiment when his trouble began, but to him his work was every-

thing, and to it he gave first his health and then his life. Last November he was compelled to relinquish his post at the Middlesex Hospital. His last service to the work and hospital he loved so well was to induce the Government to loan to the Middlesex Hospital 5 grams of radium which had been collected by the Ministry of Munitions for military purposes during the war. It may be truly said that Dr. Lyster was a martyr to science and to duty, and that it is through him and such men as him that science is enabled to triumph over disease.

2. **An Experience with the Schick Test and Toxin-Antitoxin and a Plea for Their Use in the Extinction of Diphtheria.**—Thomas E. Lilly, physician to the Industrial School for Boys at Shirley, Mass., bases his opinion of the value of the Schick test and the toxin-antitoxin as a means of exterminating diphtheria upon his four years' experience, during which time he has immunized more than one thousand persons, everyone of whom, when available, has been given the Schick test after periods varying from three months to three years from their initial dose of toxin-antitoxin, and practically everyone of whom, especially after the longer periods, give a negative Schick reaction. From this experience he holds that in institutions, schools, or communities where diphtheria has been prevalent for a considerable period of time, the universal taking of cultures, excepting in clinical cases of sore throat, is practically useless. A non-virulent bacillus is often found to be persistent in the throats of so-called chronic diphtheria carriers. Repeated passive immunization with diphtheria antitoxin does not protect families, schools, or institutions, and such immunization lasts less than three weeks. Immunity to diphtheria is both absolute and comparative. Toxin-antitoxin gives absolute immunity to diphtheria when more than one month has elapsed after its administration, causing no such troublesome and alarming reaction as antitoxin often does, the immunity persisting indefinitely. Toxin-antitoxin has no curative properties and does not immediately protect against diphtheria. In clinical cases large doses of antitoxin should be used instead of toxin-antitoxin for both patients and contacts. The Schick test is not rapid enough to be of immediate use in cases exposed to clinical diphtheria and should be used only to separate immunes from non-immunes. The Schick test and active immunization should be used in schools, camps, institutions and communities where diphtheria persists and where there is no immediate demand to protect life. The writer expresses the opinion that it is unquestionably the duty of those who have an opportunity to do so to investigate this method of immunization, and to educate the profession and the public, with the end in view of obtaining legislation compelling the administration of this prophylactic to all children upon entering school and later in life, if necessary, to obtain permanent immunization to this disease.

4. **The Eye in Pregnancy.**—Luther C. Peter asks whether the eye symptoms in pregnancy shall be regarded simply as a part of the syndrome, which a given patient may manifest, or whether these symptoms may be utilized to measure the extent of damage done to the system. In other words, may not the eye phenomena be used as a guide to the future handling of a case? He answers the question in the affirmative. Nephritis of pregnancy may be a toxemia *de novo*, superinduced by pregnancy, or it may be an acute exacerbation of a chronic interstitial nephritis precipitated by pregnancy in a nephritic patient. As the eye is one of the most definite indicators of the general progress and gravity of chronic interstitial nephritis and often one of the earliest signs, its careful study in pregnancy is equally illuminating and will help to clarify many doubtful cases. One can decide, with a fair degree of accuracy, the prognosis in a case of chronic nephritis by studying the eye grounds of the patient. This applies with equal force to the nephritis of pregnancy, but calls for the clear differentiation of the two clinical types. In the chronic variety, with an acute exacerbation brought on by or during pregnancy, the eye evidence of an old trouble is unmistakable. Some of the symptoms found are hemorrhages, retinal edema or detachment, and white stellate areas so often found in the macula in advanced cases. When the eye grounds show these marked changes, the gravid uterus, almost without exception, in the writer's opinion, should be emptied of its product of conception and promptly, without regard to the stage of the pregnancy. When, added to the other signs of chronic nephritis, there are acute toxic symptoms, diffuse retinal edema, massive hemorrhages, neuroretinitis, and swelling of the disc, a rapid termination of life is indicated unless the uterus is promptly emptied. The second type of nephritis of pregnancy is perhaps less serious in its consequences, but in some instances is just as fatal as the first. The eye symptoms are not always so pronounced, but when present they are just as easy of interpretation as in the chronic variety. Blood pressure is not so high, but it always shows some increase over what may be assumed as normal at any given age. Whether it is necessary to induce labor when the milder symptoms are present in the fundus depends largely upon the stage of the pregnancy, the blood pressure and the uranalysis. When the milder types of retinal changes are present and the blood pressure shows a moderate increase, eliminative and dietetic treatment is indicated. Kidney activity, blood pressure phenomena, and eye grounds should be watched, and a tendency to increased toxemia, as indicated especially by increased blood pressure and eye ground phenomena, should decide the question of whether to allow the patient to go to term or to interrupt pregnancy. It is to be borne in mind that marked eye ground changes may be present without the patient's knowledge or consciousness; the patient's statements or symptoms, therefore, do not always serve as guides. Not infrequently uremic blindness may suddenly be precipitated without any demonstrable eye ground changes, and eclampsia may or may not be developed. If convulsions supervene, the course of action is perfectly clear, but if they do not follow promptly there may be a desire on the part of the physician to postpone radical treatment, and eliminative measures may be tried. The writer cautions against such a course. If hysterical blindness can be excluded and a diagnosis of uremic amaurosis is evident with or without demonstrable eye ground changes, whether convulsions have already set in or are in abeyance, there can be but one line of treatment indicated, namely, prompt termination of labor. The decision as to how long one shall wait for the termination of labor, therefore, is one which can be made only by a careful weighing of evidence, the evidence of greatest value in a fair proportion of cases being that which is derived from a study of the eyes. Other symptoms which may be of assistance are puffiness of the eyelids, dimness of vision, and chemosis or edema of the conjunctiva.

2. Effects of Typhoid Fever and Typhoid Vaccine on Pulmonary Tuberculosis.—E. E. Clovis and G. E. Mills report their experience in an epidemic of typhoid fever at the State Tuberculosis Sanatorium, Terra Alta, W. Va., during August and September, 1919. Sixteen persons were infected during the epidemic at this institution, nine of whom were patients. As five of these were outside employees and were nontuberculous they are not included in the report. The conclusion of the effects of the typhoid fever on pulmonary tuberculosis in this series of eleven cases was made two months following convalescence. Of this number four were classed as active with abnormal temperature prior to the typhoid infection, and all were far advanced. Two of the four cases have continued to advance, and judging from a report received, the condition of one patient who returned home has also advanced, but in no case more rapidly than before the onset of typhoid. The remaining patient has shown a slight improvement in general condition. Three of the total cases were classed as active without rise of temperature but with other symptoms, as cough, streaked sputum, and pleurisy. Two of these patients have shown improvement in their general condition, while the condition of the other is unchanged. Three of the remaining four cases were classed as quiescent, and the other as apparently arrested. Two of these patients have shown steady improvement in both pulmonary and general condition. One has shown improvement in general condition, while there is no appreciable change in the condition of the other. With one exception the patients were weighed as soon as they were able to be weighed, and it was found that eight had lost from five to twelve pounds and that one had actually gained five pounds, while the weight of the others remained the same. In studying the effects of typhoid vaccine on pulmonary tuberculosis it was found that a higher percentage of inactive cases gave a mild reaction than the active cases. As was expected, the active cases gave a higher percentage of moderate and severe reactions than the inactive. From the study of these cases the writers draw the following conclusions: 1. The coexistence of these diseases should require a high caloric feeding. 2. Prolonged bed rest during convalescence is advisable as a precautionary measure. 3. Typhoid vaccine gave severe reactions only in the active cases, but with no permanent bad effects. 4. Patients with inactive pulmonary tuberculosis may have typhoid fever without any detrimental effects on the pulmonary condition, while the general condition may often be benefited. 5. Patients with active pulmonary tuberculosis may have typhoid fever and recover without a more rapid advance in the pulmonary condition than would have occurred had they not had typhoid fever. 6. Pulmonary tuberculosis did not have any appreciable effect on the course of the typhoid fever.

10. The Tonsil in Relation to Infectious Processes.—David John Davis included in his study of this subject the distribution of the lymphoid tissue, the protective mechanism of the lymphoid tissue, the surface area of the tonsils, the plasma cells, and the bacterial flora of tonsillar crypts. He summarizes these studies as follows: In order to understand clearly the genesis of certain diseases, it is necessary to study intensively a suspected focus of infection, like the tonsil, in both normal and infected persons. Lymphoid structures attain two maxima of distribution: one in the throat and another in the region of the ileocecal valve and appendix; these maxima correspond in general to the normal distribution of bacteria in the alimentary canal. At these points also the greatest number of pathogenic microorganisms attack the body. Plasma cells appear shortly after birth (therefore after infection) under the mucosa, and their presence probably indicates chronic absorption of infectious and other material. Certain organisms injected into the crypts of the tonsils disappear in a few days. The flora normally found in the tonsils is a restricted one. Actinomyces-like granules, composed of fusiform bacilli, streptococci and spirochetes growing together, appear as more or less normal inhabitants of the crypts. Here may be an important source of *B. fusiformis* in certain infections about the mouth caused by this organism. In the tonsil crypts, *Streptococcus hemolyticus* is almost constantly found. This focus is one source of these organisms in the throat and adjacent structures. This fact may be considered in making throat cultures and in a study of the problem of hemolytic streptococcus carriers.
